ABSTRACT: Recent developments in the Standard Model analysis of semileptonic charged-current processes involving light quarks have revealed $\sim 3\sigma$ tensions in Cabibbo universality tests involving meson, neutron, and nuclear beta decays. In this paper, we explore beyond the Standard Model explanations of this so-called Cabibbo Angle Anomaly in the framework of the Standard Model Effective Field Theory (SMEFT), including not only low-energy charged current processes ('L'), but also electroweak precision observables ('EW') and Drell-Yan collider processes ('C') that probe the same underlying physics across a broad range of energy scales. The resulting 'CLEW' framework not only allows one to test explanations of the Cabibbo Angle Anomaly, but is set up to provide near model-independent analyses with minimal assumptions on the flavor structure of the SMEFT operators. Besides the global analysis, we consider a large number of simpler scenarios, each with a subset of SMEFT operators, and investigate how much they improve upon the Standard Model fit. We find that the most favored scenarios, as judged by the Akaike Information Criterion, are those that involve right-handed charged currents. Additional interactions, namely oblique operators, terms modifying the Fermi constant, and operators involving right-handed neutral currents, play a role if the CDF determination of the W mass is included in the analysis.

Contents

1 Introduction

Precision studies of semileptonic charged-current (CC) interactions involving light quarks, mediating decays of mesons, neutrons, and nuclei, provide stringent tests of the Standard Model (SM) and its possible extensions. Prominent examples are the precision tests of lepton universality and quark-lepton (Cabibbo) universality [1]. The latter is encoded in the SM by the first-row unitarity relation for the Cabibbo-Kobayashi-Maskawa (CKM) [1, 2] matrix:

$$\Delta_{\mathrm{CKM}} \equiv |V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 - 1 = 0 \,. \tag{1.1}$$

β decays and kaon decays allow one to extract V_{ud} and V_{us} with fractional uncertainties of 0.03% and 0.22% respectively [3], leading to an uncertainty of $\sim 5 \times 10^{-4}$ in $|V_{ud}|^2 + |V_{us}|^2$, thus making $|V_{ub}|^2 \simeq 1.5 \times 10^{-5}$ largely irrelevant for this test. In the last few years, mainly due to the evolution of the theoretical input on radiative corrections in β decays [4–9] and on the $K \to \pi$ vector matrix element in lattice QCD [10–12], several tensions have emerged with the SM interpretation of semileptonic decays and Cabibbo universality. These are collectively dubbed the Cabibbo Angle Anomaly (CAA). The two main features of the CAA can be summarized as follows: first, the best-fit value of $\Delta_{\mathrm{CKM}} = -1.48(53) \times 10^{-3}$, as obtained, for example, in [13], deviates from zero at the 3σ level. Second, the extractions of V_{us} from $K \to \pi\ell\nu$ and V_{us}/V_{ud} from $\Gamma(K \to \mu\nu)/\Gamma(\pi \to \mu\nu)$ are by themselves inconsistent with CKM unitarity at the 3σ level.

This state of affairs has generated significant activity on two fronts. On the one hand, the community continues to scrutinize the theoretical aspects of the SM analysis, which involves non-perturbative input for radiative corrections and more generally for hadronic and nuclear matrix elements [13–25]. On the other hand, there is interest in looking for new physics scenarios that might explain the CAA, should it persist [26–39]. On the latter front, previous work has been rooted both in specific extensions of the SM and in effective field theory (EFT) approaches. In turn, EFT approaches have followed different strategies. Motivated by phenomenological considerations or specific classes of BSM scenarios, several groups have analyzed the CAA within a subset of the dimension-six SMEFT operators that can affect semileptonic decays [27–31, 33], with a global analysis still missing. In a different approach, refs. [40, 41] performed a global analysis of low-energy charged-current data (including τ decays in ref. [42]) using the full semileptonic operator basis in the EFT valid below the weak scale (LEFT). The LEFT analysis by construction loses the correlation of charged-current

precision measurements with other electroweak precision observables, which is explicit when using SMEFT operators that are invariant under $SU(2) \times U(1)$.

In this work, we fill the gap described above by presenting a global SMEFT analysis of the possible BSM origins of the CAA. This forces us to look at the CAA in conjunction with other observables that have sensitivity to (a subset of the) SMEFT operators that affect semileptonic charged-current decays. It turns out that a minimal analysis requires including two additional sets of observables: (i) traditional electroweak precision observables (EWPO), which are affected by vertex corrections and four-lepton operators (shifting the Fermi constant G_F) also appearing in β decays; (ii) LHC charged-current and neutral-current (NC) Drell-Yan (DY) processes, namely $pp \to \ell \bar{\nu}_\ell + X$ and $pp \to \ell \bar{\ell} + X$, which are affected by semileptonic four-fermion operators and vertex corrections also appearing in β decays. To achieve a self-consistent analysis, we should consider the complete set of SMEFT operators that affect low-energy CC processes, EWPO, and Drell-Yan processes, which is larger than the set that affects only β decays. Note that by considering the EWPO we are also forced to confront the so-called W mass anomaly [43].[1]

Given the considerations above, it is evident that the CAA and EWPO are interconnected. Thus, a comprehensive analysis accounting for all constraints should encompass observables from collider processes ('C'), low-energy ('L') charged-current processes, and electroweak precision observables ('EW'). We will refer to this as a 'CLEW' analysis. The relevance of the CLEW analysis framework can be appreciated by noting the following:

- If one focuses on BSM explanations of the CAA and only considers low-energy CC observables, it is possible to select BSM scenarios that are incompatible with EWPO and LHC Drell-Yan measurements. Only a global CLEW analysis down-selects explanations of the CAA which are compatible with constraints from weak and TeV scales.

- Similarly, it has been shown that explanations of the W mass anomaly that focus only on EWPO can select SMEFT parameters that aggravate the CAA [44, 45].

Although the CLEW framework was originally motivated by explaining anomalies in low-energy charged-current processes, it is set up to perform nearly global SMEFT fits to the precision observables that do not involve flavor-changing neutral currents (FCNC) and CP violation. Consequently, in the majority of this work, we will assume that all Wilson coefficients are real. CP violation and some of the constraints from EDMs and meson decays are briefly discussed at the end of section 9.1. Our framework can be further extended in the future to include other precision measurements, such as low-energy neutral-current phenomena (e.g. atomic parity violation or parity-violating electron scattering) and semileptonic τ decays. We currently do not include these additional observables because they either have lower precision or constrain combinations of SMEFT operators that are orthogonal to the ones affecting low-energy charged-current processes (see section 3.2 for details).

In SMEFT analyses, one has to confront the proliferation of parameters when considering the most general flavor structure of the Wilson coefficients. This is usually dealt with by imposing flavor symmetries. We start by presenting our results for a 'warm-up' scenario

---

[1]In light of tensions in the W mass measurements, we have performed the analysis both with and without the CDF 2022 result [43].

in which we impose the U(3)^5 flavor symmetry on the SMEFT Wilson coefficients. This is instructive because it closely parallels existing analyses. However, as we will discuss, this assumption is quite restrictive and can lead to inconsistencies with low-energy observables if they are not explicitly included in the analysis. We then present a general 'flavor-assumption-independent' analysis, which is highly desirable because it avoids any model dependence. We achieve this by focusing on a certain subset of Wilson coefficients that contribute to the CLEW observables, but (mostly) leave FCNC processes unaffected. The main challenge in setting up such an analysis is the need to decouple CC observables from FCNC observables (EWPO and FCNC are relatively easily decoupled) by suitable choices of independent Wilson coefficients. Although exact decoupling is not possible, we will describe a plausible scenario and possible ways to test it in the future, with extended fits that include FCNC observables.

Based on the identified set of SMEFT operators and Wilson coefficients, we then analyze the CAA systematically. We present a global fit with up to 37 independent operators and use the Akaike Information Criterion (AIC) to investigate whether fits with fewer operators perform better. We then identify, without making flavor assumptions, which set of SMEFT operators provides the optimal resolution to the CAA.

The paper is organized as follows. In section 2 we set up the framework of our analysis, identifying the operators and observables that we consider. In section 3 we describe our strategy to deal with flavor structure and set up three classes of analyses in addition to the SM analysis. In section 4 we summarize the statistical tools used in our work. We present our results in sections 5–8 providing a discussion of the main features driving the various fits. Apart from discussing the nearly-global analysis, we also consider a number of simpler scenarios that involve subsets of SMEFT operators and investigate which one leads to the most favored solution of the CAA. In section 9, we explore the potential of future measurements and theoretical developments to probe the nonzero couplings, which the statistical analysis identifies as the simplest explanation for the CAA. We offer our conclusions and outlook in section 10, while technical details are provided in the appendices. We collect the results of the 'flavor-assumption-independent' fit in the Supplemental Material.

2 Analysis framework

2.1 Standard Model Effective Field Theory

Assuming that BSM physics appears at a scale Λ well above the electroweak scale, $\Lambda \gg v$, its effects can be captured by an EFT. If the BSM dynamics is weakly coupled, the resulting TeV-scale effective Lagrangian linearly realizes the electroweak symmetry SU(2) × U(1) and contains an SM-like SU(2) Higgs doublet. The relevant EFT is the SMEFT [46, 47], which extends the SM with operators of canonical dimension $d > 4$, suppressed by powers of Λ^{4-d}. The first BSM operator appears at dimension five [48] and gives rise to neutrino Majorana masses. The leading contributions to the observables of interest in this work arise from dimension-six operators Q_i, which are described by the following effective Lagrangian

$$\mathcal{L} = \mathcal{L}_{\text{SM}} + \sum_i C_i Q_i \,, \tag{2.1}$$

where the Wilson coefficients, C_i, have mass dimension -2. There are 2499 operators in SMEFT at dimension six [49], and we adopt the widely used *Warsaw basis* [47]. As discussed

in the Introduction, our analysis includes only the operators that affect low-energy CC (semi)leptonic processes, EWPO, and Drell-Yan at the LHC. We list the relevant operators in table 1 along with the classes of observables to which they contribute, making it clear that a joint analysis of these three classes of observables is required for consistency.

Our notation is such that $l^T = (\nu_L, e_L)$ and $q^T = (u_L, d_L)$ stand for left-handed lepton and quark SU(2) doublets, while $u = u_R$, $d = d_R$, and $e = e_R$ are the right-handed up-type, down-type, and charged-lepton fields. We use p, r, s, t for generation indices and work in a basis in which the electron and down-quark Yukawa matrices are diagonal. This implies that the fields $d_{L,R}$, $e_{L,R}$ correspond to the mass eigenstates, while for the up-type quarks we have $u_L = V^\dagger u_L^{\mathrm{mass}}$, where V is the CKM matrix.[2] For further details of our notation, we refer to appendix A.

In this work, we will mainly be concerned with the SMEFT Lagrangian at tree level and only consider loop effects to include sizable QCD corrections at leading-log accuracy. This affects only the operators in the $(\bar{L}R)(\bar{L}R)$ and $(\bar{L}R)(\bar{R}L)$ classes in table 1. We will evaluate these coefficients at a renormalization scale of $\mu = 1\,\mathrm{TeV}$ when presenting the results. We use the Lagrangian in eq. (2.1) to make predictions for observables at or above the electroweak scale, such as the W mass, Z-pole observables, and Drell-Yan production cross sections. In the EWPO analysis, we choose our input parameters as the Fermi constant G_F, extracted from muon decay, the Z mass, m_Z, and the fine-structure constant, α_{em}.

To predict the low-energy charged current processes in terms of the Wilson coefficients C_i of eq. (2.1), we switch to the LEFT [50], the low-energy EFT valid below the weak scale. This is formally done by integrating out the heavy SM fields and matching the operators in eq. (2.1) to an $SU(3)_c \times U(1)_{em}$-invariant Lagrangian relevant for kaon, pion, and β decays. The matching to this Lagrangian, and the translation to conventions often used in the literature, are discussed in appendix A.2.

2.2 Observables

The choice of SMEFT operators included in the fits is dictated by the observables that we want to analyze. The observables fall into three classes: low-energy CC (semi)leptonic processes (L), electroweak-precision observables (EW), and collider probes such as Drell-Yan at the LHC (C).

2.2.1 Low-energy charged-current observables

We include semileptonic processes involving electrons and muons mediated by light quark (u, d, s) charged-current interactions. Relevant observables involve measurements of neutron and nuclear β decays as well as pion and kaon decays.

Neutron and nuclear β decays:

We closely follow the analysis of ref. [51] and take into account the neutron lifetime, $0^+ \to 0^+$ transitions, and mirror decays. Within the SM, these measurements determine V_{ud}, which, when combined with the extraction of V_{us} discussed below, currently leads to a deviation from CKM unitarity. In SMEFT, these measurements are sensitive to new vector and scalar interactions. Apart from the decay rates, we consider correlation measurements,

---

[2]We will not be concerned with neutrino mass effects in the current work, implying we do not distinguish between neutrino mass and flavor eigenstates.

Table 1. The dimension-six SMEFT operators (in the Warsaw basis [47]) that are relevant for our analysis, with subscripts p, r, s, t indicating weak-eigenstate generation indices. The last three columns indicate which observables the operators contribute to. 'L' stands for the neutron, nuclear, and meson decays discussed in appendices B.2.1 and B.2.2; 'EW' stands for the electroweak precision observables of appendix B.1; 'C' stands for the $pp \to \ell\ell$ and $pp \to \ell\nu$ processes discussed in appendix B.3.

such as those between neutrino and electron momenta $\sim \vec{p}_e \cdot \vec{p}_\nu$, described by the coefficient a, or between nuclear spin and electron momentum $\sim \vec{p}_e \cdot \vec{J}$, captured by the coefficient A. These measurements allow one to extract the ratio of vector-to-axial couplings g_A/g_V, and are sensitive to different combinations of SMEFT interactions.

The β-decay observables considered are listed in appendix B.2.1. We include them in the fit using a χ^2 function provided by the authors of ref. [51]. An important subset of them, especially with respect to CAA, are the $\mathcal{F}t$ values of superallowed transitions. For a transition, i, these values are proportional to the inverse of the decay rate, $1/\Gamma_i$, with transition-dependent phase-space factors and radiative corrections taken out. Their theoretical predictions can be written as

$$\mathcal{F}t_i = \frac{4\pi^3 \log 2}{M_F^2 m_e^5} \left[C_V^2 \pm 2 C_V C_S \gamma_i \left\langle \frac{m_e}{E_e} \right\rangle_i \right]^{-1}, \tag{2.2}$$

where the upper (lower) sign corresponds to a β^- (β^+) decay and the Fermi matrix element is $M_F^2 = 2$ for $0^+ \to 0^+$. Here

$$C_V = \sqrt{2} G_F V_{ud} g_V \sqrt{1 + \Delta_R^V}(1 + \epsilon_L^{ed} + \epsilon_R^{ed}), \qquad C_S = \sqrt{2} G_F V_{ud} g_S \epsilon_S^{ed}, \tag{2.3}$$

and $\gamma_i = \sqrt{1 - \alpha^2 Z_i^2}$, with Z the atomic number of the final-state nucleus. The Wilson coefficients are given in terms of the ϵ_i that vanish in the SM, but are generally nonzero in SMEFT, see appendix A.2. The second term in square brackets arises from the so-called b Fierz interference term, where $\langle m_e/E_e \rangle_i$ denotes the averaged ratio m_e/E_e. This term vanishes in the SM, but receives corrections from non-standard scalar interactions in SMEFT. C_V and C_S depend on the nucleon vector and scalar charges, g_V and g_S, and short-distance radiative corrections, Δ_R^V, see appendix B.2.1. The latter have recently been the subject of several re-evaluations [4–8, 18, 24], and we use the value from ref. [4].

To take into account the theoretical uncertainties associated with the transition-dependent corrections, we follow the treatment in ref. [51]. Uncertainties enter eq. (2.2) through $\mathcal{F}t_i = (1 + \delta_R')(1 + \delta_{NS}^V - \delta_C^V)ft_i$, with ft_i denoting the uncorrected values of ft. Here δ_R' represents long-distance radiative corrections, δ_{NS}^V captures nuclear-structure-dependent effects, and δ_C^V is an isospin-breaking correction. The theoretical uncertainties related to these corrections are then taken into account through

$$\mathcal{F}t_i^{\text{th.}} = \mathcal{F}t_i^{\text{expt.}}(1 + \eta_1 \Delta \delta_R'^i + \eta_2 \Delta \delta_{NS,A} + \eta_3 \Delta \delta_{NS,E}^i), \tag{2.4}$$

where $\eta_{1,2,3}$ are treated as Gaussian parameters with a 1σ confidence interval of $\eta_i \in [-1, 1]$. The uncertainty $\Delta \delta_R'^i$ is taken to be one third of the $Z^2 \alpha^3$ term in $\delta_R'^i$ [52–54], while $\Delta \delta_{NS,A} = 3.3 \cdot 10^{-4}$ [55], and $\Delta \delta_{NS,E}^i = 0.8 \cdot 10^{-4} Q/\text{MeV}$ [56], with Q the transition energy. In practice, the uncertainties related to η_1 turn out to be negligible [51]. For the 'experimental' values, $\mathcal{F}t_i^{\text{expt.}}$, we use the results of ref. [55], while we employ the theoretical expressions of ref. [51] for the left-hand side of eq. (2.4). As we will see below, the CAA will often manifest itself through nonzero values of Δ_R^V and $\eta_{2,3}$. In such cases, the theory predictions are unable to accommodate the measured rates of $0^+ \to 0^+$ without significantly altering the corrections due to δ_i.

Kaon and pion decays. We closely follow ref. [40] and organize the two-body decays into a decay rate, $\Gamma(K \to \mu\nu_\mu)$, and three ratios, $R_\pi = \Gamma(\pi \to e\nu_e)/\Gamma(\pi \to \mu\nu_\mu)$, $R_K = \Gamma(K \to e\nu_e)/\Gamma(K \to \mu\nu_\mu)$, and $R_\mu = \Gamma(K \to \mu\nu_\mu)/\Gamma(\pi \to \mu\nu_\mu)$, see table 16 for their values. In the SM, the ratio R_μ allows for a precise determination of V_{us}/V_{ud}. Going beyond the SM, all two-body decays receive contributions from axial and pseudoscalar SMEFT operators.

The two-body rate for a pseudoscalar meson P is given by

$$\Gamma_{P\ell 2} = \frac{G_F^2 |\tilde{V}_{uD}^\ell|^2 f_{P\pm}^2}{8\pi} m_{P\pm} m_\ell^2 \left(1 - \frac{m_\ell^2}{m_{P\pm}^2}\right)^2 (1 + \delta_{\text{em}}^{P\ell})(1 + \Delta_{\ell 2}^P), \tag{2.5}$$

where $m_{P\pm}$ and $f_{P\pm}$ are, respectively, the meson mass and decay constant, $\delta_{\text{em}}^{P\ell}$ captures radiative corrections, and

$$\tilde{V}_{uD}^\ell = \left(1 + \epsilon_L^{\ell D} + \epsilon_R^{\ell D} - \epsilon_L^\mu\right) V_{uD},$$
$$\Delta_{\ell 2}^P = -4\epsilon_R^{\ell D} - \frac{2m_{P\pm}^2}{m_\ell(m_u + m_D)}\epsilon_P^{\ell D} + \mathcal{O}(v^4/\Lambda^4), \tag{2.6}$$

where $D = d, s$ for $P = \pi, K$ and the coefficients ϵ_i denote the contributions of the SMEFT operators, see appendix A.2 for details. We see that $\Gamma(\pi \to \ell\nu_\ell)$ and $\Gamma(K \to \ell\nu_\ell)$ stringently constrain pseudoscalar interactions whose contributions are enhanced by a factor of $(m_{P\pm}^2)/[m_\ell(m_u + m_D)]$, where $\ell = \{e, \mu\}$.

For the three-body decays, we include the rates of $\pi^+ \to \pi^0 e\nu_e$, $K \to \pi e\nu_e$, and $K \to \pi\mu\nu_\mu$. The latter two kaon modes determine V_{us} in the SM, while all these three-body decays are sensitive to vector, scalar, and tensor SMEFT interactions. For total rates, we have

$$\Gamma_{K\ell 3} = \frac{G_F^2 m_K^5}{192\pi^3} C_K S_{\text{ew}} |\tilde{V}_{us}^\ell|^2 f_+(0)^2 I_K^\ell (1 + \delta^c + \bar{\delta}_{\text{em}}^{c\ell})^2, \tag{2.7}$$

where $C_K = 1/2$ or 1 for charged or neutral kaons. S_{ew}, δ^c, and $\bar{\delta}_{\text{em}}^{c\ell}$ denote short-distance, isospin, and radiative corrections. In practice, we do not use the theoretical determinations of δ^c, and $\bar{\delta}_{\text{em}}^{c\ell}$ in our analysis. Instead, we employ the results of ref. [57], which provides determinations of the combinations $f_+(0)|\tilde{V}_{us}^\ell|$. Finally, $f_+(0)$ is the $K \to \pi$ form factor at zero momentum, while I_K is the phase-space integral that depends on the BSM scalar and tensor interactions. In addition, we use measurements of the shape of the spectrum in these K_{l3} decays to constrain the scalar and tensor operators. The experimental and theoretical inputs required are collected in appendix B.2.2.

2.2.2 Electroweak precision observables

We include the 'traditional' observables measured at the Z pole [58]. These include the decay widths, asymmetries, and the hadronic cross section obtained from $e^+ e^- \to Z \to \bar{q}q$, as well as the W mass. As noted earlier, the recent CDF determination of m_W [43] deviates significantly from the SM and the average of other measurements [3]. Therefore, in our analyses we will consider two scenarios, one assuming the CDF determination and one where we use the world average value in PDG. In addition, we include several measurements at hadron colliders of processes at electroweak-scale energies, such as the branching ratios of the W boson and asymmetries in $pp \to \bar{\ell}\ell$ [59, 60].

Some of the traditional EW observables are measured at the sub-permille level and provide precise determinations of SM parameters, like m_Z, as well as stringent tests of the SM predictions. Due to their sensitivity to BSM physics, the study of EWPO in the SMEFT has received considerable attention [61–68]. Recent analyses have highlighted the important interplay between EWPO, Higgs observables, and diboson production at the LHC [69–72], the role of dimension-eight SMEFT operators [73, 74], and the implications of quark flavor assumptions [59, 60, 75]. Beyond the SM, the traditional EW observables receive mainly corrections from operators that contribute to the fermion-Z couplings, i.e. operators in the $\psi^2 H^2 D$ class in table 1. The additional observables from hadron colliders are helpful in closing free directions that would otherwise appear when considering SMEFT scenarios that do not assume flavor universality. The observables used, as well as the relevant SM predictions, are collected in appendix B.1 and table 12.

2.2.3 Collider probes

The measurement of Drell-Yan tails at the LHC has also been shown to be an effective probe of BSM interactions, allowing us to probe semileptonic effective operators with different quark and lepton flavors [76–79]. These constraints are complementary to those derived from low-energy flavor-physics observables. To incorporate Drell-Yan observables into our analysis, we implement the Mathematica package `HighPT` [80, 81], which includes the cross sections for Drell-Yan dilepton ($pp \to \bar{\ell}\ell$) and mono-lepton ($pp \to \bar{\ell}\nu$) searches by ATLAS and CMS, see appendix B.3 for details. `HighPT` includes the SMEFT contributions to the cross sections at LO in QCD, with detector effects simulated with `Pythia8` and `Delphes3`. Although NLO QCD effects have been shown to be important, reaching up to 30% at high invariant mass [78], the LO bounds are sufficient to provide a good estimate of the LHC sensitivity. The SM and SMEFT DY predictions are affected by theoretical uncertainties, induced, for example, by errors on the parton distributions or the omission of QCD corrections. Since the DY sensitivity relies on large deviations from the SM shape, rather than on a high-precision comparison with the SM prediction, and the uncertainty in high-transverse or invariant-mass bins is dominated by experimental uncertainties, we neglect these theory errors in our analysis.

In principle, the dimension-six operators can induce corrections to the cross section that scale as $\sim |C_i|^2 \sim v^4/\Lambda^4$. Such terms formally appear at the same order as genuine dimension-eight operators, which are not included in this work. Therefore, we only take into account SMEFT effects up to $\mathcal{O}(v^2/\Lambda^2)$ for most of this work. Although not fully consistent, we will make an exception in section 7 to estimate the sensitivity of the LHC to (pseudo)scalar operators, whose contributions vanish at $\mathcal{O}(1/\Lambda^2)$. In the future, it will be interesting to extend the study to $\mathcal{O}(1/\Lambda^4)$ in a consistent manner [82–84].

3 Analysis strategy

While the SMEFT framework provides a powerful tool to systematically and model-independently perform a global analysis of particle physics experiments involving a broad range of energies, there are technical difficulties towards a practical implementation. The main complication is the large number of independent operators, for example, the 2499 baryon-number-conserving operators at dimension six. Even after restricting the operator

structures to a subset of the full basis as done in table 1, which focuses on the CLEW observables, including all generation indices leads to an unmanageable number of Wilson coefficients. This problem is often circumvented by making certain flavor and CP assumptions on the operator basis. For example, the fit of EWPO can be greatly simplified if one assumes a global $U(3)^5$ flavor symmetry. This assumption implies that only 10 operators affect EWPO at tree level [66] (more operators appear if loop corrections are implemented [75]). Similarly, CP-invariance is often assumed as well.

These assumptions are not fully satisfactory as they essentially reintroduce model dependence into the analysis. The downside of using a strong flavor assumption is that it can miss interesting BSM explanations of anomalies. For example, as we shall see, the CAA can be nicely explained by right-handed charged current operators in up-down and up-strange transitions [13, 27, 85]. However, the corresponding SMEFT operators are forbidden under $U(3)^5$ and are strongly suppressed within minimal flavor violation (MFV) [86]. Entire classes of BSM models, such as left-right symmetric models, are automatically discarded [87], demonstrating that the analysis is no longer model independent.

Here, our goal will be to mitigate this loss of model independence, which is introduced when flavor assumptions are made, as much as possible. To achieve this, the first task is to identify the most general set of Wilson coefficients, denoted by C_n, that affect the CLEW observables discussed in section 2.2 and table 1. As we shall see, some of these couplings, denoted by $\tilde{C}_k$, unavoidably affect observables not included in our analysis as well, such as FCNC. A truly global analysis would thus need to include measurements of FCNCs explicitly, along with the CLEW observables discussed here. However, we will argue that due to the strength of FCNC constraints on the $\tilde{C}_k$ coefficients and the fact that the contributions of $\tilde{C}_k$ to the CLEW observables are in many cases suppressed by powers of the Cabibbo angle $\lambda \sim 0.2$, the global fit can be approximated by setting $\tilde{C}_k = 0$ in our analysis. This makes use of the approximate decoupling of the global analysis into smaller fits, in particular, into flavor-changing and flavor-conserving sectors. This corresponds to an approximate factorization of the likelihood function. Consequently, we expect that the constraints on C_n orthogonal to $\tilde{C}_k$ remain largely unchanged in a truly global fit.

In the following, we identify the Wilson coefficients relevant for the $U(3)^5$ and flavor-assumption-independent analyses, and present the associated fitting scenarios.

3.1 $U(3)^5$

To compare with the existing literature and highlight possible drawbacks, we first consider a scenario based on the symmetry group of flavor universality, namely $U(3)_l \times U(3)_e \times U(3)_q \times U(3)_u \times U(3)_d$. This flavor symmetry imposes strong constraints on the operators in table 1. For the couplings that contribute to EWPO, neglecting terms proportional to the SM Yukawa couplings, one finds the following relations

$$C_{Hl}^{(1,3)} \propto \mathbf{1}, \qquad C_{He} \propto \mathbf{1} \qquad C_{Hq}^{(1,3)} \propto \mathbf{1}, \qquad C_{Hu} \propto \mathbf{1}, \qquad C_{Hd} \propto \mathbf{1}. \qquad (3.1)$$

For operators that involve right-handed fields and contribute to low-energy CC observables, the flavor symmetry implies

$$C_{Hud} = C_{ledq} = C_{lequ}^{(1,3)} = 0. \qquad (3.2)$$

Semileptonic four-fermion operators involving left-handed fields induce 9 terms, all with the same Wilson coefficient

$$C_{lq}^{(3)} \propto \mathbf{1}_\ell \times \mathbf{1}_q \,. \tag{3.3}$$

In the purely leptonic sector, Q_{ll} involves two bilinears with the lepton field L. In this case, we can write two invariant structures

$$[C_{ll}]_{ij\ell m} \propto C_0 \delta^{ij}\delta^{\ell m} + \hat{C}_{ll}\delta^{im}\delta^{\ell k} \,. \tag{3.4}$$

C_0 does not induce charged-current decays of the muon or τ lepton, and, in particular, does not affect G_F. $\hat{C}_{ll} = [C_{ll}]_{1221} = [C_{ll}]_{1331} = [C_{ll}]_{2332}$ affects muon decay and the extraction of G_F. In the case of U(3)^5, the corrections to $\mu \to e\bar{\nu}_e\nu_\mu$, $\tau \to e\bar{\nu}_e\nu_\tau$, and $\tau \to \mu\bar{\nu}_\mu\nu_\tau$ are the same, such that the effect of $\hat{C}_{ll}$ on the lepton decays becomes invisible if G_F is used as input parameter. Finally, purely bosonic operators, Q_{HD} and Q_{HWB} also affect the EWPO. However, it turns out that these contributions always appear in fixed combinations with the vertex corrections in eq. (3.1). They therefore do not increase the effective number of fit parameters, see section 6 for details.

In summary, for this scenario we will consider a set of 9 Wilson coefficients involving the couplings in eq. (3.1) and (3.3) together with $\hat{C}_{ll}$.

3.2 Flavor-symmetry independent analysis

The first step towards a flavor-assumption-independent analysis is to identify the most general set of Wilson coefficients that affect the CLEW observables, allowing for a general flavor structure, starting from table 1. To this end, we need to pick a basis, and we find it convenient to phrase the discussion in terms of the quark-mass basis, which is reached from the weak basis by simply replacing $u_L \to V^\dagger u_L$, where V is the CKM matrix. In addition, it will be useful to identify the couplings that give rise to neutral-current interactions. In the quark mass basis, the induced couplings of up- and down-type quarks to the Z boson are given by the following linear combinations of Wilson coefficients

$$C_{Hq}^{(u)} = V\left[C_{Hq}^{(1)} - C_{Hq}^{(3)}\right]V^\dagger \,, \qquad C_{Hq}^{(d)} = C_{Hq}^{(1)} + C_{Hq}^{(3)} \,. \tag{3.5}$$

Similarly, the semileptonic Wilson coefficients appear as

$$C_{lq}^{(u)} = V\left[C_{lq}^{(1)} - C_{lq}^{(3)}\right]V^\dagger \,, \qquad C_{lq}^{(d)} = C_{lq}^{(1)} + C_{lq}^{(3)} \,, \qquad \bar{C}_{lequ}^{(1,3)} = VC_{lequ}^{(1,3)} \,, \tag{3.6}$$

where $C_{lq}^{(u)}$ and $\bar{C}_{lequ}^{(1,3)}$ represent the neutral-current couplings between up-type quarks and charged leptons, while $C_{lq}^{(d)}$ and C_{ledq} control the neutral currents between down-type quarks and charged leptons.

The contributions of these new Wilson coefficients to CLEW observables can be read off in a straightforward way in the case of EWPO and neutral-current Drell-Yan, which involve the diagonal entries of the above couplings. On the other hand, $d, s \to u$ transitions in CC processes, such as β-decay and CC Drell-Yan, are sensitive to the combinations ($D = d, s$)

$$\begin{aligned}
&\left[VC_{Hq}^{(d)} - C_{Hq}^{(u)}V\right]_{uD} \,, \qquad \left[VC_{lq}^{(d)} - C_{lq}^{(u)}V\right]_{\ell\ell uD} \,, \\
&\left[VC_{ledq}^\dagger\right]_{\ell\ell 11} \,, \qquad \left[VC_{ledq}^\dagger\right]_{\ell\ell 22} \,, \qquad \left[\left(\bar{C}_{lequ}^{(1,3)}\right)^\dagger V\right]_{\ell\ell 11} \,.
\end{aligned} \tag{3.7}$$

These combinations depend on off-diagonal Wilson coefficients, thus inducing 'cross-talk' with FCNC observables not included in our analysis. Now we discuss the impact of these probes in greater detail.

Contributions of left-handed interactions to CC processes are proportional to

$$V_{uD}\epsilon_L^{\ell D} = \frac{v^2}{2}\left[VC_{Hq}^{(d)} - C_{Hq}^{(u)}V\right]_{uD} - \frac{v^2}{2}\left[VC_{lq}^{(d)} - C_{lq}^{(u)}V\right]_{\ell\ell uD}. \tag{3.8}$$

Neglecting terms that are suppressed by more than one power of $\lambda \equiv V_{us}$, only a few off-diagonal couplings are expected to contribute without CKM suppression,

$$\epsilon_L^{\ell d} \simeq \frac{v^2}{2}\left[C_{Hq}^{(d)} - C_{Hq}^{(u)} + \frac{V_{us}}{V_{ud}}C_{Hq}^{(d)} - \frac{V_{cd}}{V_{ud}}C_{Hq}^{(u)}\right] - (C_{Hq} \to C_{lq}),$$

$$\epsilon_L^{\ell s} \simeq \frac{v^2}{2}\left[\frac{V_{ud}}{V_{us}}C_{Hq}^{(d)} - \frac{V_{cs}}{V_{us}}C_{Hq}^{(u)} + C_{Hq}^{(d)} - C_{Hq}^{(u)} - \frac{V_{ts}}{V_{us}}C_{Hq}^{(u)}\right] - (C_{Hq} \to C_{lq}). \tag{3.9}$$

The off-diagonal couplings are stringently constrained by the decays of pseudoscalar mesons to charged leptons. In particular, $[C_{Hq}^{(d)}]_{12,21}$ will have a large impact on kaon decays such as $K \to \pi\bar{\ell}\ell$, while $[C_{Hq}^{(u)}]_{12}$ affects the analogous D meson decays. We discuss the resulting constraints in more detail in appendix C, where the main conclusion is that the off-diagonal elements appearing in eq. (3.9) are expected to have a minimal impact on low-energy CC observables because of stringent FCNC constraints. Similarly, $[C_{Hq}^{(u)}]_{31}$ in eq. (3.9) is constrained by top-quark decays, and its contribution to $\epsilon_L^{\ell s}$ is suppressed by a factor of V_{ts}/V_{us}, so that it cannot significantly affect the low-energy CC observables. These arguments justify a basis that includes only the diagonal couplings of $C_{Hq}^{(u,d)}$.

Very similar arguments hold for the coefficients $[\bar{C}_{lequ}^{(1,3)}]^\dagger$ and $C_{ledq}^\dagger$, whose contributions to the effective low-energy couplings, $\epsilon_{S,P,T}$, have a flavor structure analogous to the $C_{Hq}^{(u)}$ and $C_{Hq}^{(d)}$ terms in eq. (3.8), respectively.

The discussion of $C_{lq}^{(u,d)}$ is somewhat more involved. Although their appearance in eq. (3.8) and (3.6) is analogous to the case of $C_{Hq}^{(u,d)}$ couplings, they differ due to the fact that these operators also induce couplings to neutrinos of the form $(\bar{\nu}\nu)(\bar{q}q)$. The flavor structures that govern neutrino interactions with up- and down-type quarks are given by

$$C_{lq}^{(\nu-u)} = VC_{lq}^{(d)}V^\dagger, \qquad C_{lq}^{(\nu-d)} = V^\dagger C_{lq}^{(u)}V. \tag{3.10}$$

Thus, off-diagonal entries of $C_{lq}^{(u,d)}$ can be stringently constrained by meson decays to charged leptons and neutrinos. The latter are discussed in more detail in appendix C, where we find that $[C_{lq}^{(\nu-d)}]_{12}$ is very stringently constrained by $K \to \pi\nu\bar{\nu}$, practically forcing $[C_{lq}^{(u)}]_{\ell\ell12} \simeq 0$ and $[C_{lq}^{(u)}]_{\ell\ell11} \simeq [C_{lq}^{(u)}]_{\ell\ell22}$.

The inclusion of low-energy CC processes in the CLEW analysis also affects the linearly independent combinations of the purely bosonic Wilson coefficients C_{HWB} and C_{HD} (directly associated with the Peskin-Takeuchi oblique parameters S and T [88]) that can be constrained by the data. While ten operators affect EWPO under $U(3)^5$, only eight linear combinations are actually constrained. We denote these combinations by $\hat{C}_i$, see eq. (6.1), which indicates

that $C_{HF}^{(3)}$, with $F = \{l, q\}$, appear in a linear combination with C_{HWB} and C_{HD}, while $C_{HF}^{(1)}$ and C_{Hf}, with $f = \{u, d, e\}$, appear in combination with C_{HD}. Since the low-energy CC observables (L) are affected by $C_{HF}^{(3)}$ but not by C_{HWB} and C_{HD} (see table 1), they break the degeneracy between $C_{HF}^{(3)}$ and $C_{HWB,HD}$ present in the EW fits. The LEW data thus constrain one linear combination of C_{HD} and C_{HWB}, which we call C_{ST}, while leaving the orthogonal direction, C_{TS}, unconstrained.

The combinations $C_{ST,TS}$ take the form

$$\begin{pmatrix} C_{ST} \\ C_{TS} \end{pmatrix} \equiv \frac{1}{\sqrt{c_w^2 + 16s_w^2}} \begin{pmatrix} 4s_w & c_w \\ -c_w & 4s_w \end{pmatrix} \begin{pmatrix} C_{HWB} \\ C_{HD} \end{pmatrix}, \tag{3.11}$$

where $s_w = \sin\theta_w$ and $c_w = \cos\theta_w$, with θ_w being the weak mixing angle. $C_{HF}^{(1)}$ and C_{Hf} do not affect the low-energy CC, but do influence the LHC observables by entering the Drell-Yan process. Their corrections to the Drell-Yan cross section exhibit the same energy dependence as the SM background. In contrast, the SMEFT 4-fermion operators give corrections with a stronger energy dependence and dominate the high-energy tail of Drell-Yan processes. Thus, although some constraints are exerted on $C_{HF}^{(1)}$ and C_{Hf} by the LHC observables, they are too weak to substantially lift the degeneracy with C_{HD}. Thus, only the linear combination C_{ST} is well constrained by our CLEW data sets. The orthogonal combination, C_{TS}, on the other hand, is poorly constrained and we do not include it.

For each class of operator in table 1 we can now summarize which Wilson coefficients should be included in a general analysis of low-energy CC and EWPO data:

- $\psi^2 H^2 D$

  For $Q_{Hl}^{(1,3)}$ and $Q_{He,Hd,Hu}$ we take into account the diagonal entries that appear in EWPO, including couplings to all flavors apart from the top. Q_{Hud} does not induce neutral currents or effects in EWPO, and we include the terms that contribute to low-energy CC processes, namely the 11 and 12 components. We include the diagonal entries of the $C_{Hq}^{(u,d)}$ coefficients that enter in EWPO or low-energy observables, again excluding the top coupling.

- $(\bar{L}L)(\bar{L}L)$

  Here, the relevant couplings include $[C_{ll}]_{1221}$ that enters through its effect on muon decay. We include the diagonal entries of the $C_{lq}^{(u,d)}$ couplings that appear in low-energy CC measurements, namely $[C_{lq}^{(u,d)}]_{\ell\ell 11}$ and $[C_{lq}^{(d)}]_{\ell\ell 22}$. In addition, we impose the constraint that these coefficients do not induce large off-diagonal entries of $C_{lq}^{(\nu-d)}$, which implies $[C_{lq}^{(u)}]_{\ell\ell pr} \propto \delta_{pr}[C_{lq}^{(u)}]_{\ell\ell pr}$. Although this does not affect low-energy observables, the existence of couplings to the heavier generations does have an effect on collider observables.

- $(\bar{L}R)(\bar{R}L)$

  Taking into account the diagonal terms that enter the low-energy measurements leads to the inclusion of $[C_{ledq}]_{\ell\ell 11}$ and $[C_{ledq}]_{\ell\ell 22}$.

- $(\bar{L}R)(\bar{L}R)$

  The same analysis tells us that we should include $[\bar{C}_{lequ}^{(1,3)}]_{\ell\ell11}$.

- Finally, we include the linear combination C_{ST} of the two purely bosonic interactions C_{HD} and C_{HWB}.

We summarize the Wilson coefficients involved in the left panel of table 2.

The above set of operators are chosen because they provide corrections to the EWPO and CC processes while not being constrained to negligible levels by FCNC constraints. Four-fermion operators give rise to contributions to Drell-Yan processes that grow with energy. They are therefore strongly constrained by measurements of the high-invariant or transverse-mass tails of the NC and CC Drell-Yan distributions. CC Drell-Yan is primarily sensitive to four-fermion operators that affect β decays at low energy, namely $[VC_{lq}^{(d)} - C_{lq}^{(u)}V]_{\ell\ell ud}$, $[VC_{lq}^{(d)} - C_{lq}^{(u)}V]_{\ell\ell us}$, $[C_{ledq}]_{\ell\ell11}$, $[C_{ledq}]_{\ell\ell22}$, and $[C_{lequ}^{(1,3)}]_{\ell\ell11}$. Operators with heavy c and b quarks do contribute to the Drell-Yan cross section, but their effects are suppressed by the heavy-quark PDFs and can, in the first approximation, be neglected. The above derived operator basis is then complete for the analysis of CC Drell-Yan processes.

Through gauge invariance, the semileptonic CC four-fermion operators in principle also contribute to NC Drell-Yan which is included in our analysis. Strictly speaking, these measurements are affected by additional operators C_{ld}, C_{lu}, C_{ed}, C_{eu}, and C_{qe} with their respective flavor indices. Including these interactions would also require the extension of the set of observables since these operators are probed by processes such as parity-violating electron-proton scattering. Here, we do not discuss these operators further because they do not modify the EWPO and low-energy CC processes. Nevertheless, explicitly including these operators would be an interesting extension of the current framework, which we leave for future work.

3.3 Three classes of analyses

Having discussed the relevant operators, we will perform fits in three different scenarios:

1. **U(3)^5 fit:** we start with a scenario assuming U(3)^5 flavor symmetry, neglecting terms involving the SM Yukawa couplings. This scenario highlights the close connection between EWPO, low-energy CC observables, and high-energy Drell-Yan processes. We will show that fits considering only a single class of observables, as often done in the literature, can lead to a poor description for observables in the other classes, and are thus inconsistent.

2. **Flavor-symmetry-independent intermediate fit:** a scenario involving only the 22 Wilson coefficients that affect low-energy CC processes and the CAA (see the right panel of table 2), but which nevertheless includes the EWPO and Drell-Yan data. Although not self-consistent, we will see that this scenario provides a good description of the data, in particular of the CAA, as long as the CDF measurement of m_W is not considered.

3. **Flavor-symmetry-independent global fit:** a global fit in which all operators in the left panel of table 2 are included.

Global analysis	Indices	Low energy CC analysis	Indices
$C_{Hl}^{(1,3)}{}_{pr}$, $\quad C_{He}{}_{pr}$	$pr \in \{ee,\, \mu\mu,\, \tau\tau\}$	$C_{Hl}^{(3)}{}_{pr}$	$pr \in \{ee,\, \mu\mu\}$
$C_{Hq}^{(d)}{}_{pr}$, $\quad C_{Hd}{}_{pr}$	$pr \in \{11, 22, 33\}$	$C_{Hq}^{(d)}{}_{pr}$	$pr \in \{11, 22\}$
$C_{Hq}^{(u)}{}_{pr}$, $\quad C_{Hu}{}_{pr}$	$pr \in \{11, 22\}$	$C_{Hq}^{(u)}{}_{11}$	
$C_{Hud}{}_{pr}$	$pr \in \{11, 12\}$	$C_{Hud}{}_{pr}$	$pr \in \{11, 12\}$
$C_{lq}^{(d)}{}_{\ell\ell pr}$, $\quad C_{ledq}{}_{\ell\ell pr}$	$\ell \in \{e, \mu\}, \quad pr \in \{11, 22\}$	$C_{lq}^{(d)}{}_{\ell\ell pr}$, $\quad C_{ledq}{}_{\ell\ell pr}$	$\ell \in \{e, \mu\}, \quad pr \in \{11, 22\}$
$C_{lq}^{(u)}{}_{\ell\ell 11}$, $\quad \bar{C}_{lequ}^{(1,3)}{}_{\ell\ell 11}$	$\ell \in \{e, \mu\}$	$C_{lq}^{(u)}{}_{\ell\ell 11}$, $\quad \bar{C}_{lequ}^{(1,3)}{}_{\ell\ell 11}$	$\ell \in \{e, \mu\}$

Table 2. Left panel: the 37 Wilson coefficients that are relevant to the global analysis, including low-energy charged-current observables, EWPO, and CC Drell-Yan as described in section 3.2. Right panel: the subset of 22 Wilson coefficients that contribute to low-energy charged-current observables as described in section 3.2.

In addition, we will consider several simpler scenarios, involving subsets of the operators, which will help build some intuition for the larger, more general analysis. In all cases, we will study the role of different sets of observables. We will label each of these analyses by the observables considered and the Wilson coefficients involved in the scenario. L denotes the low-energy CC processes related to nuclear, neutron, and meson decay; EW stands for traditionally defined electroweak precision observables (EWPO); and C (collider) stands for the Drell-Yan processes described above. For instance, the fit L22 would describe a fit of the 22 operators introduced in Scenario 2 to the low-energy CC observables only, whereas CLEW22 would correspond to the same operators, but now also including EWPO and Drell-Yan processes. For fits that include EW, we will often consider two separate cases depending on whether we include or exclude the CDF measurement of m_W.

4 Statistical tools

In the next section, we present results for a large number of fits. We will use χ^2 minimization to perform these analyses and employ the Akaike Information Criterion (AIC) [21] to compare the quality of various fits. The method of χ^2 minimization is a statistical tool commonly used to fit theoretical models to empirical data. It measures the sum of the squared differences between the observed data and the model predictions, weighted by their respective uncertainties. By minimizing the function χ^2, we obtain the best-fit parameters that most closely align the theoretical model with the experimental observations.

A χ^2-fit is performed to a given set of experimental measurements $E = \{E_1, E_2, \ldots\}$ with a covariance matrix V, where each E_i is the experimental value of an observable. We

denote the theoretical predictions for those observables as $O = \{O_1, O_2, \ldots\}$, where each O_i is a function of the model parameters. When fitting to the SM, the parameters are λ, hadronic and nuclear matrix elements appearing in low-energy observables (such as the ratio of Fermi and Gamow-Teller matrix elements in mirror transitions, see appendix B.2.1), and the parameters that capture theoretical uncertainties related to corrections in β decays, which are discussed below eq. (2.4). In SMEFT, O_i also depend on the Wilson coefficients considered in the analysis. We construct our χ^2 function by

$$\chi^2 = (O - E)^T V^{-1} (O - E) \,, \tag{4.1}$$

where V^{-1} is the inverse of the covariance matrix, which is related to the variances of the observables and their correlation matrix through, $V_{ii} = \sigma_i^2$ and $\mathrm{corr}_{ij} = \sigma_i^{-1} V_{ij} \sigma_j^{-1}$, respectively. Whenever they are available, we add theoretical calculations of hadronic and nuclear matrix elements to the χ^2 in the same way, effectively treating them as experimental measurements. Similarly, $\eta_{1,2,3}$, which appear in β decays, are also treated as Gaussian parameters, see appendix B.2.1 for details.

Minimizing the χ^2 function gives the best-fit values of the model parameters. We will take the minimum of the χ^2 of the SM as our benchmark and compare it with that of a specific set of Wilson coefficients in SMEFT. The difference of their minimal χ^2 values,

$$\Delta\chi^2 = \chi^2_{\mathrm{SM}} - \chi^2_{\mathrm{SMEFT}} \,, \tag{4.2}$$

indicates the improvement on the fit provided by SMEFT. Note that this is only a useful comparison when both χ^2_{SM} and χ^2_{SMEFT} involve the same set of observables. If the two fits include different observables, then the two minimal χ^2 values cannot be compared directly.

Generally speaking, the more parameters a model includes, such as Wilson coefficients, the lower the minimal χ^2, since the extra parameters provide more degrees of freedom to shift the theoretical predictions towards the experimental values. To compare the quality of two fits including the same set of observables but different parameters, instead of using the χ^2 per degree of freedom criterion, we apply the AIC [21].

AIC is often used in model selection. It is a measure that balances the goodness of fit of a model against its complexity. The AIC is computed using the number of parameters in the model and the maximum likelihood of the model. In our case, the AIC of a fit can be presented as

$$\mathrm{AIC} = \left(\mathrm{Minimal}\ \chi^2\right) + 2 \times (\mathrm{Number\ of\ the\ parameters}) \,, \tag{4.3}$$

where the parameters here refer to the considered Wilson coefficients and λ. Depending on the observables that are considered, the parameters may also include several matrix elements and parameters that describe theoretical uncertainties. The lower the AIC, the better the model is considered to describe the data, so the difference $\mathrm{AIC}_i - \mathrm{AIC}_j$ is a measure of the improvement of model j over i. As more parameters (such as Wilson coefficients) are added to a model, it may better fit the data, but it also becomes more complex and runs the risk of overfitting. The AIC balances these considerations by penalizing models for introducing more parameters without a corresponding decrease in $\Delta\chi^2$. Used in conjunction with the χ^2

method, AIC tends to find a model that not only fits the experimental data well but also avoids overcomplication, thus improving its predictive accuracy.

In our analysis, we will often be interested in comparing the SM fit with SMEFT scenarios. We will thus take the SM as the reference model, and define differences in AIC as

$$\Delta\text{AIC}_i = \text{AIC}_{\text{SM}} - \text{AIC}_i \,, \tag{4.4}$$

where i denotes a particular SMEFT model. Here and in what follows, we will define a 'SMEFT model' as the SMEFT with a subset of Wilson coefficients turned on, with the remaining couplings set to zero. An advantage of the definition in eq. (4.4) is that the SM parameter λ, the matrix elements, and the parameters that describe the theoretical uncertainties drop out in the calculation of ΔAIC_i. Notice that, with our definition, $\Delta\text{AIC}_i > 0$ implies that a model performs better than the SM.

In addition to the overall quality of the fit, as measured by the AIC, we are also interested in the best-fit values, uncertainties, and correlations of the Wilson coefficients and the other fit parameters. We use the fact that the observables are linear in the Wilson coefficients to rewrite

$$\chi^2 = \chi^2_{\text{min}} + (C - \mu)^T \hat{V}^{-1} (C - \mu) \,, \tag{4.5}$$

where C and μ are vectors of model parameters (Wilson coefficients) and their best-fit values, while $\hat{V}$ is the covariance matrix of the model parameters

$$(\hat{V}^{-1})_{ij} = \frac{1}{2} \frac{\partial^2 \chi^2}{\partial C_i \partial C_j}\Big|_{C=\mu} \,. \tag{4.6}$$

The uncertainties of C_i can now be read from $\hat{\sigma}_i^2 = \hat{V}_{ii}$, while the correlations between the model parameters are given by $\widehat{\text{corr}}_{ij} = \hat{\sigma}_i^{-1} \hat{V}_{ij} \hat{\sigma}_j^{-1}$.

Because $\hat{V}^{-1}$ is symmetric, it can be diagonalized by an orthogonal matrix, which implies that there are linear combinations of C_i, corresponding to the eigenvectors of $\hat{V}^{-1}$, that are not correlated. This diagonalization allows one to see which combinations of Wilson coefficients the observables are most sensitive to and which combinations are most favored to be nonzero. This diagonalization can be performed through $R^T \hat{V}^{-1} R = \hat{v}$, with $\hat{v}$ a diagonal matrix and R an orthogonal matrix. The uncorrelated combinations of Wilson coefficients and the best-fit values are given by $C' = R^T C$ and $\mu' = R^T \mu$. Here, R is determined by the eigenvectors of $\hat{V}^{-1}$, while the uncertainties of C_i' are determined by the eigenvalues of $\hat{V}^{-1}$.

4.1 Model averaging

When considering a large number of scenarios involving different sets of operators, it becomes interesting to see how (un)favored nonzero values of a particular Wilson coefficient are across different fits. One robust method to tackle this is model averaging using the AIC. Here, we follow Burnham and Anderson [89], who advocated for the assignment of weights to individual models based on their AIC scores, thus allowing the derivation of model-averaged estimates for the parameters. The weight of a model is defined by

$$w_i = \frac{e^{\frac{1}{2}\Delta\text{AIC}_i}}{\sum_j e^{\frac{1}{2}\Delta\text{AIC}_j}} \,. \tag{4.7}$$

Data sets	EW	L	C	LEW	CLEW
Number of measurements	41	53	145	94	239
Degrees of freedom for SM	41	46	145	87	232

Table 3. Number of measurements included in different data sets and the number of degrees of freedom relevant for the χ^2 analysis of the SM.

Notice that the weights w_i do not depend on the fact that we used the SM as a reference in the definition of ΔAIC_j. The quality of the models that involve a given SMEFT coefficient, θ, will be gauged by considering the sum of the weights of all the models in which θ is turned on,

$$W_\theta = \sum_i w_i I_\theta(i) \,, \tag{4.8}$$

where $I_\theta(i) = 1$ if the model, i, contains the parameter θ, and $I_\theta(i) = 0$ if it does not. For the most significant coefficients, with $W_\theta = \mathcal{O}(1)$, we will be interested in providing a model-averaged central value and an estimator of the standard deviation [89],

$$\bar{\theta} = \frac{\sum w_i I_\theta(i)\theta_i}{W_\theta}, \qquad \sigma_\theta = \frac{\sum w_i I_\theta(i)\sqrt{\sigma_{\theta_i}^2 + (\theta_i - \bar{\theta})^2}}{W_\theta} \,, \tag{4.9}$$

where θ_i and σ_{θ_i} are the best-fit value and uncertainty of the Wilson coefficient θ in model i, respectively. Wilson coefficients which have $W_\theta \ll 1$ are only present in models of poor quality, making their model-averaged values less important, and we will not consider them.

5 SM analysis

We begin our analysis by studying the Standard Model and the status of the CAA. The numbers of measurements included in the different data sets are shown in table 3. For the collider data, this represents the total number of bins extracted from the package `HighPT`. Our most comprehensive data set, CLEW, contains 239 measurements in total.

The matrix elements affecting the low-energy fit are summarized in table 15. They do not affect the number of degrees of freedom as we add a term in χ^2 for each, effectively treating the theoretical central value and uncertainty as a 'measurement'. The parameters $\eta_{1,2,3}$, which capture theoretical uncertainties in superallowed β decays, are treated in a similar manner. When counting degrees of freedom, in addition to the number of observables and the fit parameters of a model, we need to include six ratios of Fermi and Gamow-Teller matrix elements. They enter in mirror β decays and are fit at the same time as the SM and SMEFT coefficients.

We begin with the low-energy CC observables, for which the relevant degrees of freedom are $V_{us} \equiv \lambda$, as well as the six ratios of nuclear matrix elements that enter in mirror β decays. The fit aligns λ with the determinations from leptonic kaon decays. Therefore, the anomalies reside in the parameters and observables related to radiative corrections of β decays as well as semileptonic kaon decays. The resulting value for λ and the minimum χ^2 are given by

$$\lambda = 0.22497 \pm 0.00027 \,, \qquad \chi^2_{\min} = 53 \,, \qquad \chi^2/\text{d.o.f.} = 1.1 \,, \tag{5.1}$$
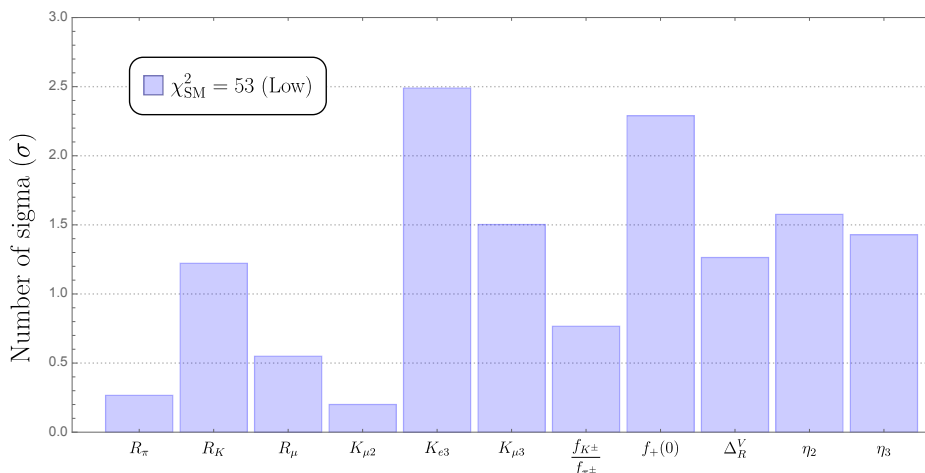

Figure 1. Chart of several low-energy CC observables, relevant to the CAA, showing the difference between the SM prediction at the best-fit point and the experimental results in units of standard deviation. For the matrix elements ($f_{K^\pm}/f_{\pi^\pm}$, $f_+(0)$ and Δ_R^V) and nuisance parameters ($\eta_{2,3}$), the chart shows the deviation from the central value of the theoretical prediction.

obtained when fitting the SM to the L observables. The fact that this fit gives a good χ^2/d.o.f. is in part due to the fact that the CAA is diluted by a large number of other observables, which mostly show good agreement with the SM. However, the subset of observables related to the extraction of V_{ud} and V_{us} still shows significant tension with the SM as indicated in eq. (1.1) and the discussions in e.g. refs. [13, 28].

In our SM analysis, the unitarity of the CKM matrix is fixed and V_{ud} and V_{us} are not independent. The CAA as presented in eq. (1.1) is then manifested in figure 1 where we show the difference (in units of standard deviation) between the SM predictions at the best-fit point and the experimental values for several observables. We also show the deviation of $f_+(0)$, f_{K^+}/f_π, and Δ_R^V and of the nuisance parameters $\eta_{2,3}$ from their preferred theoretical values. In the case of meson decays, the CAA appears mainly in $K_{\ell 3}$ decays, as the corresponding decay rates and the relevant form factor, $f_+(0)$, deviate from their experimental/theoretical values by 2.5 standard deviations. Instead, the kaon decay constant $f_{K^\pm}$, which is related to the leptonic decays (not shown in the figure), is in good agreement with the lattice determination in table 15.

For neutron and nuclear β decays, the CAA mostly shows up through deviations in the radiative corrections, Δ_R^V, and the parameters $\eta_{2,3}$, which parameterize theoretical uncertainties related to nuclear-structure dependent corrections. The observables of interest, the $\mathcal{F}t$ values for the $0^+ \to 0^+$ transitions, typically show deviations of $\lesssim 1\sigma$ and are not shown in figure 1. This means that the fit aims to align $\mathcal{F}t$ values closely with experimental determinations by selecting matrix elements and parameters $\eta_{2,3}$ that deviate from their predicted values.

Moving on to the class of EW observables, we find a minimal χ^2 of

$$\chi^2_{\min} = 42.2, \qquad \chi^2/\text{d.o.f.} = 1.1, \qquad (m_W^{\text{PDG}}),$$
$$\chi^2_{\min} = 97.9, \qquad \chi^2/\text{d.o.f.} = 2.4, \qquad (m_W^{\text{CDF}}), \qquad (5.2)$$
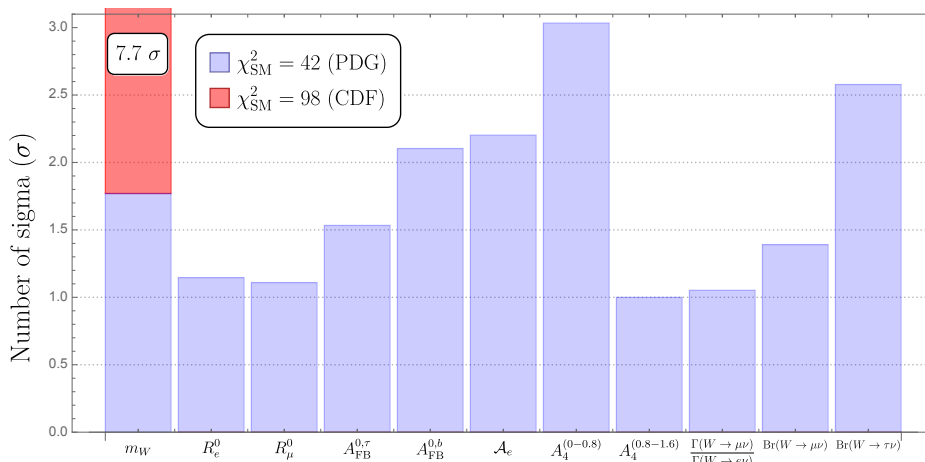

Figure 2. Observables that deviate by more than 1σ from their experimental values at the best-fit point of the EW fit. The red bar shows the 7.7σ deviation associated with the CDF value of the W mass, while the blue bars implement the PDG value.

depending on which measurement of m_W is used. We again show the discrepancy between the fit and experiment in figure 2, now for all observables with a deviation greater than 1σ. Clearly, the largest discrepancy arises in the case of m_W^{CDF}, while pulls of a few σ appear for several ratios of decay widths and asymmetries. The most significant ones appear for asymmetries measured at LEP (e.g. $A_{\mathrm{FB}}^{0,b}$ and $\mathcal{A}_e$), measurements near the Z pole at the LHC (one of the bins of the asymmetry A_4), and the branching ratio of $W \to \tau\nu$.

Finally, we consider the SM fit to the collider observables, which consist of the different CC and NC Drell-Yan processes, $pp \to \bar{\ell}\ell$ and $pp \to \ell\nu$. In turn, each of these channels involves a relatively large number of invariant and transverse mass bins. The minimal χ^2 therefore tends to be fairly large, and we find

$$\chi^2_{\mathrm{min}} = 104\,, \qquad \chi^2/\mathrm{d.o.f.} = 1.1\,. \tag{5.3}$$

The result of fitting multiple sets of observables, such as LEW or CLEW, corresponds to simply combining individual fits, which implies that the χ^2_{min} of the CLEW fit is given by the sum of eqs. (5.1), (5.2), and (5.3). This is due to the fact that only the fit to low-energy data involves free parameters in the form of λ, matrix elements, and parameters that describe theoretical uncertainties, while the EWPO and collider data are, to a good approximation, independent of these variables.

6 SMEFT analysis with U(3)⁵ flavor assumption

We start by considering a BSM scenario in which we impose a $\mathrm{U}(3)^5$ flavor symmetry on the SMEFT coefficients. Ref. [66] investigated the impact of the measurement of the CDF W mass on the EWPO fit under these assumptions. The EWPO depend on eight combinations of Wilson coefficients [63], namely $\hat{C}_{Hl}^{(1,3)}$, $\hat{C}_{Hq}^{(1,3)}$, $\hat{C}_{He}$, $\hat{C}_{Hu}$, $\hat{C}_{Hd}$, and $\hat{C}_{ll}$. As mentioned in section 3.1, the hat-notation is used to identify the linear combinations that cannot be

separated using EWPO alone:

$$\hat{C}_{HF}^{(3)} = C_{HF}^{(3)} + \frac{c_w}{s_w} C_{HWB} + \frac{c_w^2}{4 s_w^2} C_{HD} \,,$$

$$\hat{C}_{HF}^{(1)} = C_{HF}^{(1)} - \frac{Y_F}{2} C_{HD} \,,$$

$$\hat{C}_{Hf} = C_{Hf} - \frac{Y_f}{2} C_{HD} \,, \tag{6.1}$$

for $F = \{l, q\}$ and $f = \{u, d, e\}$ and $Y_{F,f}$ denotes the corresponding weak hypercharge. We follow [44] and define

$$C_\Delta = 2 \left[\hat{C}_{Hq}^{(3)} - \hat{C}_{Hl}^{(3)} + \hat{C}_{ll} \right] \,, \tag{6.2}$$

where $\hat{C}_{ll} = [C_{ll}]_{1221}$. Defining C_Δ will be useful, as it is the linear combination of Wilson coefficients that appears in the EWPO that contributes to deviations from CKM unitarity. Therefore, we will use this relation to trade $\hat{C}_{ll}$ for C_Δ. The SMEFT corrections to the W mass can be expressed in terms of these operators as [64, 90]

$$\frac{\delta m_W^2}{m_W^2} = v^2 \, \frac{s_w c_w}{s_w^2 - c_w^2} \left[2\, C_{HWB} + \frac{c_w}{2 s_w} C_{HD} + \frac{s_w}{c_w} \left(2\, C_{Hl}^{(3)} - \hat{C}_{ll} \right) \right]$$

$$= v^2 \, \frac{s_w^2}{s_w^2 - c_w^2} \left(2 \hat{C}_{Hl}^{(3)} - \hat{C}_{ll} \right) = v^2 \, \frac{s_w^2}{s_w^2 - c_w^2} \left(\hat{C}_{Hl}^{(3)} + \hat{C}_{Hq}^{(3)} - \frac{1}{2} C_\Delta \right) \,. \tag{6.3}$$

The expression of s_w in terms of the input parameters G_F, m_Z, and α_{em} is given in eq. (A.7). Finally, under the assumption of $U(3)^5$ flavor symmetry, the violation of CKM unitarity is described by

$$\Delta_{\mathrm{CKM}} = |\tilde{V}_{ud}|^2 + |\tilde{V}_{us}|^2 - 1 = v^2 \left(C_\Delta - 2 C_{lq}^{(3)} \right) \,. \tag{6.4}$$

Here, $\tilde{V}_{ij}$ are the effective CKM elements that are probed in low-energy measurements of β and K decays, while $\tilde{V}_{ub}$ can be neglected at the current level of precision. C_Δ entirely captures the contribution to Δ_{CKM} of the operators that enter EWPO, whereas $C_{lq}^{(3)}$ does not play a role in EWPO and is therefore traditionally not included.

6.1 $U(3)^5$ results *including* the CDF W mass

We begin our analysis by fitting the 8 linear combinations of Wilson coefficients to the set of EWPO defined in appendix B.1 including, in particular, the 2022 CDF measurement of the W mass. We list the best-fit values and the 1σ ranges in the EW column of table 4 labeled with EW. Within uncertainties, the results agree with refs. [44, 66]. As noted in [44], the fit value of C_Δ based on EWPO is nonzero at a significant level and corresponds to a violation of CKM unitarity. Plugging C_Δ in eq. (6.4), we find

$$\Delta_{\mathrm{CKM}}|_{\mathrm{EW}} = -0.009 \pm 0.004 \,, \tag{6.5}$$

indicating a percent-level deviation from CKM unitarity, significantly larger than allowed by current experimental determinations [44].

Table 4. U(3)^5 fit results while including the CDF m_W measurement. Coefficients are given in units of TeV^{-2}. In the EW and LEW$_1$ fits, the U(3)^5 invariant coefficient $C_{lq}^{(3)}$ is set to zero, while it is included as a fit parameter in LEW$_2$ and CLEW. The bottom three rows report several quantities that measure the quality of the fits.

We can study the impact of the Wilson coefficients in the EW column of table 4 on each of the low-energy CC observables. We do so by setting the Wilson coefficients at their central values, while floating the relevant matrix elements, the parameters that describe the uncertainties of the theory, and λ. In figure 3 we compare this scenario (in red) with the SM (in blue) and the SMEFT (in green), fit to both the EWPO and low-energy CC observables (LEW). We only show observables that change by more than 1σ from the SM fit. The red bars show that, while the U(3)^5 EW fit resolves the m_W anomaly, it leads to a very poor description of a wide range of low-energy observables when they are not explicitly included in the analysis.

To get a sensible result, we must include low-energy CC observables in the fit. This leads to the fit results in the second column of table 4. The inclusion of low-energy observables significantly reduces the value of $|C_\Delta|$, which also leads to lower values for $|\hat{C}_{Hl}^{(3)}|$ and $|\hat{C}_{Hq}^{(3)}|$. This confirms the conclusion of ref. [44] that the m_W-anomaly, in general, cannot be studied using EWPO alone. The modified fit leads to a much improved description of the low-energy CC observables as can be seen by comparing the red and green bars in figure 3.

It can be argued that the above conclusion is too strong. Even within the U(3)^5 flavor symmetry it is possible to decouple the EWPO from the low-energy CC observables by including $C_{lq}^{(3)}$ in the fit, as can be seen from eq. (6.4). We demonstrate this in the third
Figure 3. Comparison of three scenarios in the description of EWPO and low-energy CC observables, *including* the CDF measurement of m_W marked by a deviation of 7.7σ. In blue, we denote the results of a SM fit to the LEW data. The red bars correspond to a SMEFT fit to just the EW data, under the flavor assumption of $U(3)^5$. The last three red bars, Δ_R^V, η_2, and η_3, have off-the-charts deviations greater than 6σ. The green bars correspond to a $U(3)^5$ SMEFT fit to the LEW data.

column of table 4 where we observe in the EW and LEW columns that a nonzero value of $C_{lq}^{(3)}$ can absorb violations of CKM unitarity, while leaving the other Wilson coefficients unchanged.

Although this may seem to be a reasonable resolution of both the m_W anomaly and the CAA, significant values of $C_{lq}^{(3)}$ modify the Drell-Yan processes measured at the LHC. To test whether this leads to relevant deviations of the high-p_T tails of Drell-Yan processes, we include the observables in table 17. The fit results[3] are given in the CLEW column of table 4 and we see that the LHC observables essentially force $|C_{lq}^{(3)}| \leq 10^{-3}\,\text{TeV}^{-2}$, far too small to compensate for any significant low-energy effects induced by the other Wilson coefficients. The resulting CLEW values in table 4 then exactly agree with the values of the LEW_1 column in the same table.

The quality of the fits are also shown at the bottom of table 4. The $U(3)^5$ fit to the LEW observables (corresponding to the LEW_1 column) gives $\Delta\chi^2 = 73$ and $\chi^2_{\text{SMEFT}}/\text{d.o.f.} = 1.0$, which implies a very good fit and an improvement over the SM, $\Delta\text{AIC} = 57$. The CLEW fit that includes $C_{lq}^{(3)}$ gives a slightly worse $\Delta\text{AIC} = 55$ due to the addition of a fit parameter.

The large difference between the SM and $U(3)^5$ fits is mainly driven by the CDF determination of m_W. This is reflected in the nonzero values of several Wilson coefficients, with three of them at 3 to 4σ: $\hat{C}_{Hl}^{(3)}$, $\hat{C}_{Hq}^{(3)}$, and $\hat{C}_{He}$. Their values in the first column (EW) of table 4 can be understood from the relation

$$\hat{C}_{Hl}^{(3)} + \hat{C}_{Hq}^{(3)} = \frac{1}{v^2}\left(1 - \frac{c_w^2}{s_w^2}\right)\frac{\delta m_W^2}{m_W^2} + \frac{1}{2}C_\Delta \simeq -0.15\,\text{TeV}^{-2}, \tag{6.6}$$

which agrees well with the best-fit point

$$\hat{C}_{Hl}^{(3)} + \hat{C}_{Hq}^{(3)} = -(0.152 \pm 0.047)\,\text{TeV}^{-2}. \tag{6.7}$$

---

[3]We have checked that adding additional $U(3)^5$-invariant four-fermion operators that only affect Drell-Yan processes but not the LEW observables, does not change this conclusion.

The value of $\hat{C}_{He}$ can be understood from the SMEFT correction to the partial width of the Z boson that decays into right-handed electrons [91]

$$\frac{\delta\Gamma(Z \to e_R\,\bar{e}_R)}{\Gamma(Z \to e_R\,\bar{e}_R)} = \frac{v^2}{c_w^2 - s_w^2}\left[\frac{2c_w}{s_w}C_{HWB} + \frac{1}{2}C_{HD} + \left(2\,C_{Hl}^{(3)} - \hat{C}_{ll}\right) + \frac{s_w^2 - c_w^2}{s_w^2}C_{He}\right]$$

$$= -\frac{v^2}{s_w^2 - c_w^2}\left(2\,\hat{C}_{Hl}^{(3)} - \hat{C}_{ll}\right) - \frac{v^2}{s_w^2}\hat{C}_{He}$$

$$= -\frac{1}{s_w^2}\left(\frac{\delta m_W^2}{m_W^2} + v^2\hat{C}_{He}\right), \qquad (6.8)$$

where $\Gamma(Z \to e_R\,\bar{e}_R)$ is derived from the total width R_e^0 and the forward-backward asymmetry factor $\mathcal{A}_e$. Therefore,

$$\hat{C}_{He} = -\frac{1}{v^2}\left[\frac{\delta m_W^2}{m_W^2} + s_w^2\frac{\delta\Gamma(Z \to e_R\,\bar{e}_R)}{\Gamma(Z \to e_R\,\bar{e}_R)}\right] \simeq -0.026\,\mathrm{TeV}^{-2}, \qquad (6.9)$$

which roughly agrees with the best-fit value of $\hat{C}_{He} = -(0.024 \pm 0.0086)\,\mathrm{TeV}^{-2}$ in the first column (EW) of table 4.

Finally, $\hat{C}_{Hd} = -(0.54 \pm 0.25)\,\mathrm{TeV}^{-2}$ in table 5 is approximately 2σ from zero (this is true even without the CDF measurement of m_W, see below), which is caused by the discrepancy in the forward-backward asymmetry of the bottom quark, $A_{\mathrm{FB}}^{0,b}$ (see figure 2). This leads to [91]

$$\hat{C}_{Hd} = -\frac{1}{3v^2}\left[\frac{\delta m_W^2}{m_W^2} + s_w^2\frac{\delta\Gamma(Z \to b_R\,\bar{b}_R)}{\Gamma(Z \to b_R\,\bar{b}_R)}\right] \simeq -0.55\,\mathrm{TeV}^{-2}. \qquad (6.10)$$

6.2 U(3)^5 results *without* the CDF W mass

We briefly investigate the impact on the above results if we use the world average value of the W mass in PDG, $m_W = 80.377 \pm 0.012\,\mathrm{GeV}$. The SM fit to the LEW data results in the blue bars of figure 4 corresponding to a total $\chi_{\mathrm{SM}}^2 = 95$ ($\chi_{\mathrm{SM}}^2/\mathrm{d.o.f.} = 1$) with an information criterion of $\mathrm{AIC}_{\mathrm{SM}} = 97$. By excluding CDF m_W, the total χ^2 has been reduced by 56 (see section 5), but there is still tension remaining due to the CAA.

We then performed a SMEFT fit to the EWPO (see the EW column in table 5) and predicted the corresponding low-energy CC observables. Similar to the previous section, this results in a fit that alleviates minor discrepancies in the EWPO (such as m_W), but it provides an unsatisfactory description of the low-energy CC processes. Instead, if we perform a SMEFT LEW fit, we obtain the LEW column of table 5 corresponding to the green bars in figure 4. This fit gives $\chi_{\mathrm{SMEFT}}^2 = 74$ ($\Delta\chi^2 = 21$ and $\chi_{\mathrm{SMEFT}}^2/\mathrm{d.o.f.} = 0.9$). It has a better $\Delta\mathrm{AIC} = 7$ than the SM fit and addresses the CAA through C_Δ, which is nonzero at the 3σ level. From figure 4, we see that C_Δ reduces the tension in superallowed β decays, but cannot accommodate $K_{\ell3}$ at the same time. Compared to the fit using $m_W(\mathrm{PDG})$, the result for C_Δ remains the same. However, the 3σ deviations in $\hat{C}_{Hl}^{(3)}$, $\hat{C}_{He}$, $\hat{C}_{Hq}^{(3)}$ disappeared. This is not surprising, as all were driven by the value of m_W measured by CDF.

	EW	LEW

6.3 Intermediate conclusions

The first conclusion is that within the $U(3)^5$ scenarios it is not possible to decouple the EWPO from the low- and high-energy CC observables. These observables depend on an overlapping set of Wilson coefficients and have a similar sensitivity to BSM physics. We have shown that fitting the SMEFT Wilson coefficients to the EWPO only, irrespective of whether the CDF measurement of m_W is included or not, generally leads to unacceptably large BSM effects in low-energy β and meson decay processes. Furthermore, due to the pronounced sensitivity of CC Drell-Yan, semileptonic four-fermion operators cannot offset these effects. We are forced to combine the sets of observables. Given this perspective, the conventional set of EWPO, as discussed in the literature, is no longer adequate. We recommend consistently incorporating both low- and high-energy CC observables. Similar conclusions were reached in refs. [44, 45, 92, 93].

That being said, the inclusion of CDF m_W obviously affects the fit results. Taken at face value, it clearly shows that the SM provides a poor fit. We find that a U(3)^5 scenario can simultaneously account for the m_W anomaly and part of the CAA. This fit performs significantly better than the SM with $\Delta\text{AIC} = 57$ and requires four Wilson coefficients that are 3–4σ away from zero, which provides a clue for model building in U(3)^5 scenarios. We stress that different values of these coefficients will be obtained if the EWPO observables are considered in isolation, which leads to severe problems in the description in the low-energy CC observables, as shown in figure 3.

Excluding the CDF measurement, the picture is less clear. While the U(3)^5 LEW fit can partially accommodate the CAA — as evidenced by the enhanced descriptions of neutron, nuclear, and meson decays — this improvement is offset by the inclusion of additional fit parameters. When the dust settles, the AIC of the U(3)^5 fit is still better ($\Delta\text{AIC} = 7$) than the SM fit due to a partial resolution of the CAA.

7 Flavor-independent intermediate fit and the CAA in SMEFT

In this section, we consider scenario 2 of section 3.3 which focuses on the CAA and *excludes* the CDF m_W. We have argued that an analysis that does not rely on theoretical assumptions regarding the flavor structure of BSM physics involves 37 independent SMEFT operators, 22 of which contribute to the low-energy CC processes. In the following, we start by discussing scenarios including the 22 Wilson coefficients that affect the low-energy observables. Although we will perform a global fit to the CLEW observables of all 22 Wilson coefficients, the results are not straightforward to interpret. We will first explore several more focused fits, considering only a subset of operators. This approach will assist in dissecting the results and offer guidance for model building.

7.1 Right-handed operators

The analysis of the CKM anomaly performed in ref. [13] indicated that right-handed (RH) charged-current interactions could provide a viable explanation for the CAA. These interactions are induced by the SMEFT operator Q_{Hud}, which is forbidden under U(3)^5 and strongly suppressed in MFV scenarios. We consider two independent Wilson coefficients $[C_{Hud}]_{11,12}$ and, when fitting to low-energy CC observables, we refer to this fit as L2(RH). The results can be found in the L2(RH) column of table 6, showing nonzero values of the RH up-down and up-strange interactions at more than 3σ, with a small correlation between the two couplings, see figure 5 for details.

The corresponding eigenvectors are given by

$$0.28\, C_{\substack{Hud\\11}} + 0.96\, C_{\substack{Hud\\12}} = -0.011 \times (4.2 \pm 1)\,\text{TeV}^{-2}\,,$$

$$0.96\, C_{\substack{Hud\\11}} - 0.28\, C_{\substack{Hud\\12}} = -0.0076 \times (2.1 \pm 1)\,\text{TeV}^{-2}\,, \tag{7.1}$$

and thus, respectively, 4.2σ and 2.1σ away from zero.

Compared to the SM fit, the minimal χ^2 decreased from 52 to 30, an improvement of $\Delta\chi^2 = 22$, which implies $\Delta\text{AIC(RH2)} = 18$. In the left panel of figure 6, we display the
Figure 5. Results of the L2(RH) fit to low-energy CC observables involving two Wilson coefficients $[C_{Hud}]_{11}$ and $[C_{Hud}]_{12}$, given in units of TeV^{-2}. Three contours illustrate the likelihoods of 1, 2, and 3σ. The best-fit point is marked by a yellow cross, whereas the origin (the SM point) is marked by a blue dot.

observables that show improvement over the SM fit. Specifically, the RH currents align the three-body kaon decays as well as nuclear β decays with observations, as evidenced by the Δ^V_R values and the $\eta_{2,3}$ parameters.

7.2 Scalar/pseudoscalar operators

Scalar/pseudoscalar currents also influence the charged-current processes that determine V_{ud} and V_{us}. As shown in appendix A.2, there are six relevant Wilson coefficients that enter at tree level. We label the fit to them as L6(SPS) and present the results in table 6 and the middle panel of figure 6.
Figure 6. Difference between the theoretical predictions at the best-fit point and the experimental results or the theoretical central values, for observables and matrix elements relevant to low-energy CC data. The blue bars represent the SM results, while the red bars correspond to three SMEFT fits. Only SMEFT bars that differ by more than 1σ from the SM are shown. Left: L2(RH). Center: L6(SPS). Right: L8(RS).

There are strong correlations between the different contributions. In the case of semileptonic couplings to electrons, the pseudoscalar operators give contributions to R_π and R_K (defined as $R_{\pi,K} = \Gamma_{\pi,K\to e\nu_e}/\Gamma_{\pi,K\to\mu\nu_\mu}$) that are enhanced by $m_{\pi,K}^2/[m_e(m_u+m_{d,s})]$ with respect to the SM. As a consequence, the combinations $([C_{ledq}]_{1111} - [\bar{C}_{lequ}^{(1)}]_{1111})$ and $([C_{ledq}]_{1122} - [\bar{C}_{lequ}^{(1)}]_{1111})$ are severely constrained. The scalar combination $([C_{ledq}]_{1111} + [\bar{C}_{lequ}^{(1)}]_{1111})$ affects $0^+ \to 0^+$ transitions and must be nonzero to address the CAA. For the couplings to muons, the contributions to R_π and R_K are only enhanced by $1/m_\mu$, so the correlations are weaker, while the scalar combination $([C_{ledq}]_{2222} + [\bar{C}_{lequ}^{(1)}]_{2211})$ affects $K_{\mu3}$. This discussion can be neatly summarized by studying the eigenvectors of the fit:

σ (TeV^{-2})	μ/σ	C_{ledq} 1111	C_{ledq} 1122	C_{ledq} 2211	C_{ledq} 2222	$\bar{C}_{lequ}^{(1)}$ 1111	$\bar{C}_{lequ}^{(1)}$ 2211
$2.7 \cdot 10^{-6}$	0.2	-0.62	-0.15	0	0	0.77	0
$5.8 \cdot 10^{-6}$	1.2	0.53	-0.8	0	0	0.28	0
$1.5 \cdot 10^{-3}$	0.9	0	0	0.79	-0.2	0	-0.58
$1.7 \cdot 10^{-3}$	1.8	0	0	0.23	-0.78	0	0.58
$6.7 \cdot 10^{-3}$	1.1	0	0	0.57	0.59	0	0.57
$1.1 \cdot 10^{-2}$	2.3	-0.58	-0.58	0	0	-0.58	0

where μ and σ denote the best-fit values and uncertainties of the eigenvectors. The eigenvectors reflect the correlations argued above, but also show that the picture is more complicated than having a single eigenvector that is clearly nonzero.

The main differences between the L2(RH) and L6(SPS) fits can be seen from the two left panels of figure 6. L2(RH) helps to resolve discrepancies in the three-body kaon decay processes, specifically K_{e3} and $K_{\mu3}$. Additionally, it brings the $\eta_{2,3}$ parameters associated with $0^+ \to 0^+$ transitions closer to their predicted central values. L6(SPS) can also alleviate, but to a lesser degree, the tensions in the three-body kaon decays, while also removing the small tension in $R_K = \Gamma(K \to e\nu_e)/\Gamma(K \to \mu\nu_\mu)$. However, this introduces extra tension in the superallowed β decay of ^{14}O and pushes the $\eta_{2,3}$ parameters further away from their
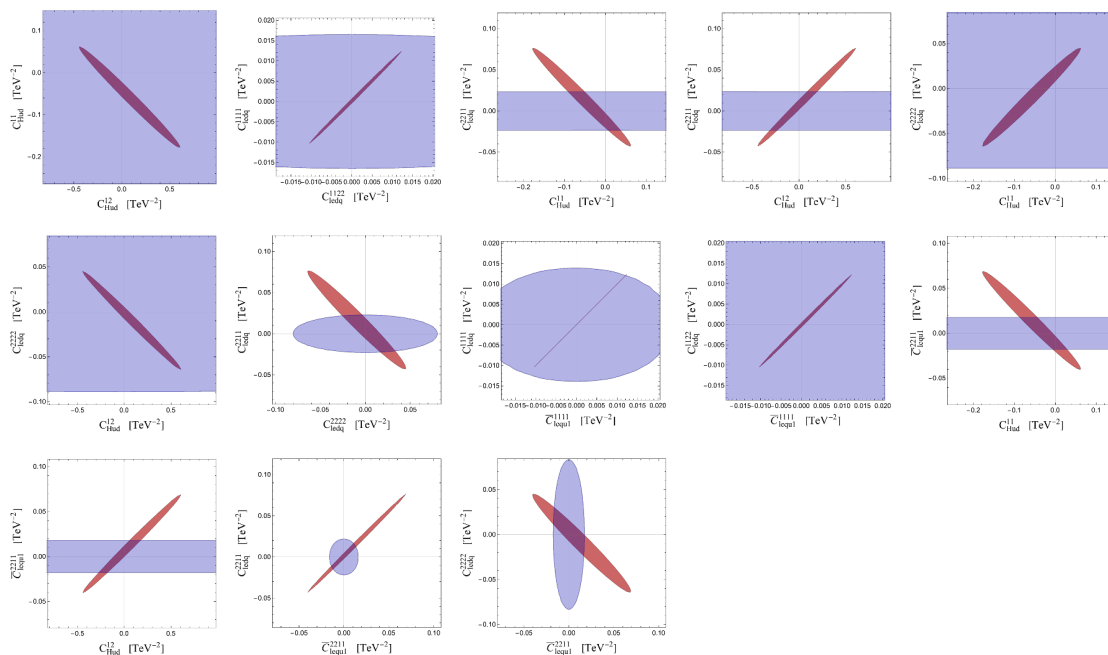

Figure 7. The 1σ allowed region in the L8(RS) scenario, shown for several 2D slices in parameter space. The red and blue regions correspond to those preferred by the low-energy CC and collider observables, respectively.

central values. Taken together, the fit of L6(SPS) yields a ΔAIC ≈ 0, making its performance on par with the SM, but significantly inferior to L2(RH).

Combining RH + SPS operators. We now combine the two RH operators and the six pseudoscalar ones to perform an L8(RS) fit. The results show $\Delta\chi^2 = 25$, which is slightly higher than L2(RH), at the price of six additional Wilson coefficients and thus a worse ΔAIC $= 9$. The relevant observables are shown in the right panel of figure 6. We observe that L8(RS) closely mirrors L2(RH), with scalar/pseudoscalar interactions offering a slight improvement of R_K.

All best-fit values in L8(RS) are consistent with zero within 1σ. The larger deviations from zero appearing in L2(RH) have been diluted due to the additional operators. However, as shown in figure 7, several of the operators in L8(RS) are highly correlated. For example, $[C_{Hud}]_{11}$ and $[C_{Hud}]_{12}$ are negatively correlated in L8 (RS), while they have almost no correlation in L2(RH). In fact, if $[C_{Hud}]_{12} = 0$ then $[C_{Hud}]_{11} < 0$ by approximately 3σ. These correlations demonstrate a strong interplay between the right-handed and scalar/pseudoscalar operators, which affects the options for model building. Although we do not show all the eigenvectors, it is worth noting that L8(RS) features a distinct eigenvector that almost reaches the 4σ level

$$0.77 C_{\substack{Hud \\ 11}} + 0.1 C_{\substack{ledq \\ 2222}} + 0.18 C_{\substack{Hud \\ 12}} + 0.35 \left(C_{\substack{ledq \\ 1111}} + C_{\substack{ledq \\ 1122}} + \bar{C}^{(1)}_{\substack{lequ \\ 1111}} \right) = -0.0076 \times (3.9 \pm 1)\, \text{TeV}^{-2},$$

while all other eigenvectors have a significance of less than 2σ. Interestingly, compared to L2(RH), this eigenvector is dominated by the up-down right-handed current operator ($[Q_{Hud}]_{11}$) instead of the up-strange one ($[Q_{Hud}]_{12}$) that appears in L2(RH).
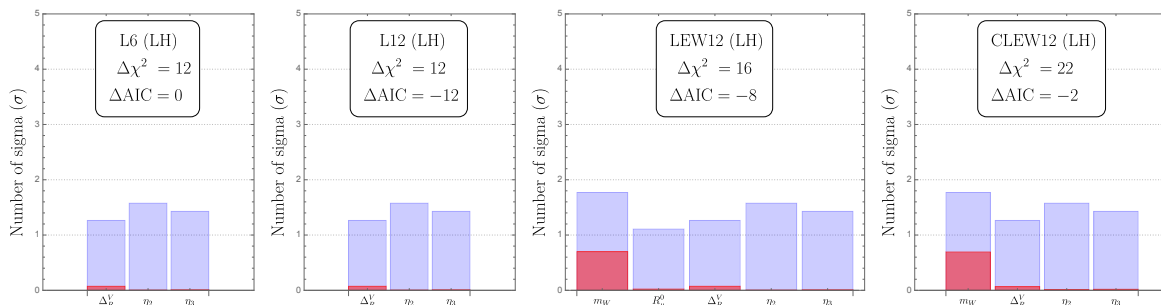

Figure 8. Same as figure 6, for four different SMEFT models. From left to right: L6(LH), L12(LH), LEW12(LH), and CLEW12(LH).

All fits conducted with only right-handed and scalar/pseudoscalar operators remain robust when expanding to a broader set of observables. Neither the RH nor the pseudoscalar operators enter the EWPO or the collider data at linear order. As such, CLEW2(RH), CLEW6(SPS), and CLEW8(RS) give the same results as previously reported.

Although the operators do not enter the collider observables at linear order, they do contribute quadratically. To achieve a fully consistent analysis that includes these effects, one must also consider genuine dimension-eight operators, as they formally emerge at the same order. Such an analysis is beyond the scope of this work. However, we would like to nonetheless gauge the sensitivity of the collider observables. To do so, we consider the constraints set by the Drell-Yan measurements on the quadratic contributions assuming that only the L8(RS) Wilson coefficients are turned on. The resulting constraints are shown by the blue regions in figure 7, along with the region preferred by the low-energy data in red. These preliminary collider constraints are beginning to explore areas of the parameter space not yet ruled out by low-energy CC measurements. However, the collider processes have not probed any of the nonzero values favored by the low-energy observables.

7.3 Left-handed operators and vertex corrections

Left-handed operators. Another way to explain the CKM anomaly could involve modifications of the left-handed charged currents. We investigate this by turning on the six Wilson coefficients associated with left-handed semileptonic four-fermion operators: $C_{lq}^{(u)}$ and $C_{lq}^{(d)}$. The fit, termed L6(LH), yields $\Delta\chi^2 = 12$, which is on par with L6(SPS) and does not offer an improvement in AIC compared to the SM. The pattern of observables differs between fits, as shown in the left panel of figure 8. L6(LH) essentially requires less tension in the $\eta_{2,3}$ parameters related to radiative corrections in superallowed β decays, but does not address the tension in kaon observables. The sole eigenvector with a notable nonzero value is given by

$$0.69 C_{\substack{lq \\ 1111}}^{(d)} - 0.72 C_{\substack{lq \\ 1111}}^{(u)} = 0.0059 \times (3.1 \pm 1)\,\mathrm{TeV}^{-2}\,. \qquad (7.2)$$

In contrast to earlier fits, L6(LH) is not stable under the inclusion of more observables. The four-fermion operators do not modify EWPO but they do affect Drell-Yan processes at the LHC. After taking into account the latter, $\Delta\chi^2$ reduces to 7. This results in a less favorable $\Delta\mathrm{AIC} = -5$ relative to the SM, suggesting that the left-handed four-fermion operators needed to address the CAA conflict with high-energy measurements.

Vertex Corrections	LEW
$[C_{Hud}]_{11}$	-0.0047 ± 0.049
$[C_{Hud}]_{12}$	-0.037 ± 0.013
$[\hat{C}^{(3)}_{Hl}]_{11}$	-0.0057 ± 0.0059
$[\hat{C}^{(3)}_{Hl}]_{22}$	-0.0063 ± 0.0052
$[\hat{C}^{(u)}_{Hq}]_{11}$	0.23 ± 0.41
$[\hat{C}^{(d)}_{Hq}]_{11}$	0.20 ± 0.44
$[\hat{C}^{(d)}_{Hq}]_{22}$	-0.010 ± 0.12

Table 7. Best fit for LEW7(V) including right- and left-handed vertex corrections. Wilson coefficients are given in units of TeV^{-2}.

The stability under the inclusion of LHC data might improve if we expand to the full set of SMEFT operators that affect LH currents. We name the fit L12(LH). It encompasses the six operators of L6(LH) as well as the operators associated with vertex corrections $[C^{(3)}_{Hl}]_{ee}$, $[C^{(3)}_{Hl}]_{\mu\mu}$, $[C^{(d)}_{Hq}]_{11}$, $[C^{(d)}_{Hq}]_{22}$, $[C^{(u)}_{Hq}]_{11}$, and the purely leptonic four-fermion operator $[C_{ll}]_{2112}$. As far as the low-energy CC observables are concerned, the additional six operators are redundant. We can see this by comparing the first two panels on the left in figure 8, which are identical. However, once we move to LEW12 (3rd panel on the left in figure 8), the additional operators can reduce tension in the EWPO, in particular m_W and $R_{0\mu}$, leading to a greater $\Delta\chi^2 = 16$. If we also include the LHC data (the panel on the right of figure 8), we see that $\Delta\chi^2$ of CLEW12 grows to 22. This increase is not tied to a singular observable, but results from minor changes across multiple bins. However, even with these improvements, the AIC of CLEW12 falls short compared to the SM, yielding $\Delta\text{AIC} = -2$. This further underscores that purely left-handed SMEFT operators do not provide an effective solution to the CAA.

Vertex corrections. We have seen that LHC measurements can strongly constrain the semileptonic four-fermion operators. In light of this, we will investigate SMEFT operators that provide vertex corrections, which are less stringently probed by DY measurements. Of the 22 operators discussed in this section, only seven belong to this category: $[C^{(3)}_{Hl}]_{ee,\mu\mu}$, $[C^{(d)}_{Hq}]_{11,22}$, $[C^{(u)}_{Hq}]_{11}$, and $[C_{Hud}]_{11,12}$. We will fit them to the low-energy CC observables and the EWPO simultaneously, naming it LEW7(V), with V signifying vertex.

The best-fit values are given in table 7, while the impact on the observables is shown in figure 9. The value of $[C_{Hud}]_{12}$ is close to that obtained in L2(RH), indicating that the RH up-strange interaction accounts for the kaon processes. The role of $[C_{Hud}]_{11}$, however, is diluted by left-handed vertex corrections that can also modify β-decay processes. In fact, the only eigenvector that is nonzero at more than 2σ is given by

$$0.96 C_{Hud\atop 12} + 0.12 \hat{C}^{(3)}_{Hl\atop 22} - 0.19 \hat{C}^{(u)}_{Hq\atop 11} + 0.18 \hat{C}^{(d)}_{Hq\atop 11} = -0.011 \times (3.9 \pm 1)\,\text{TeV}^{-2}, \qquad (7.3)$$

which is dominated by the up-strange RH current.

LEW7(V) has a $\Delta\chi^2 = 27$ compared to the SM, which is slightly better than LEW2(RH) due to mild improvements in m_W (too small to appear in figure 9) at the price of five additional operators. This leads to $\Delta\text{AIC} = 13$, compared to 18 for the L2(RH) scenario.
Figure 9. Same as figure 6, for two different fits involving right- and left-handed vertex corrections. Left: LEW7(V) *without* the CDF m_W. Right: LEW7(V) *including* the CDF m_W.

One advantage of LEW7(V) is its ability to partially reconcile with the CDF measurement of m_W, see the right panel of figure 9.

7.4 The full 22 fit

Now we turn the crank and fit all 22 operators simultaneously. For L22, we obtain $\Delta\chi^2 = 26$, only slightly better than L8(RS). This is reflected in the left panels of figures 10 and 6. The L22 fit allows for essentially the same improvements over the SM as L8(RS), while the additional small gain in $\Delta\chi^2$ is due to a slightly better description of the neutron lifetime and R_K. When moving to LEW22, we see that, similar to LEW12(LH), the additional operators can account for some small discrepancies in the EWPO, again mainly for m_W and $R_{0\mu}$. Moving to CLEW22, we find another small improvement of $\Delta\chi^2$, but the pattern of observables essentially stays the same, and therefore we only show the results for CLEW22 in figure 10.

Moving from L22 to LEW22 and finally to CLEW22 significantly reduces the number of free directions in the fit. The resulting central values, uncertainties, and correlations can be seen explicitly in the Supplementary Material. In particular, in CLEW22 there are no free directions remaining and the magnitudes of each Wilson coefficient are constrained below $1/\mathrm{TeV}^2$. All Wilson coefficients are consistent with zero within 2σ, while three eigenvectors emerge, which deviate more than 2σ from zero. These linear combinations involve a large number of Wilson coefficients. Truncating the contributions to the normalized eigenvectors at 0.3, we find

$$0.42\,C^{(u)}_{\substack{Hq\\11}}-0.40\,C^{(d)}_{\substack{Hq\\11}}-0.37\left(C^{(3)}_{\substack{Hl\\22}}+C_{\substack{Hud\\11}}\right)-0.59\,\bar{C}^{(3)}_{\substack{lequ\\1111}}=0.0091\times(2.4\pm1)\,\mathrm{TeV}^{-2},$$

$$0.60\,C^{(3)}_{\substack{Hl\\22}}-0.58\,C_{\substack{ll\\2112}}-0.30\,C_{\substack{ledq\\2222}}=0.0025\times(3.1\pm1)\,\mathrm{TeV}^{-2},$$

$$-0.96\,C^{(3)}_{\substack{Hl\\11}}=0.0051\times(2.9\pm1)\,\mathrm{TeV}^{-2}. \qquad (7.4)$$

However, the CLEW22 fit has the worst information criterion with $\Delta\mathrm{AIC} = -7$, indicating that adding more parameters is simply not worth it.
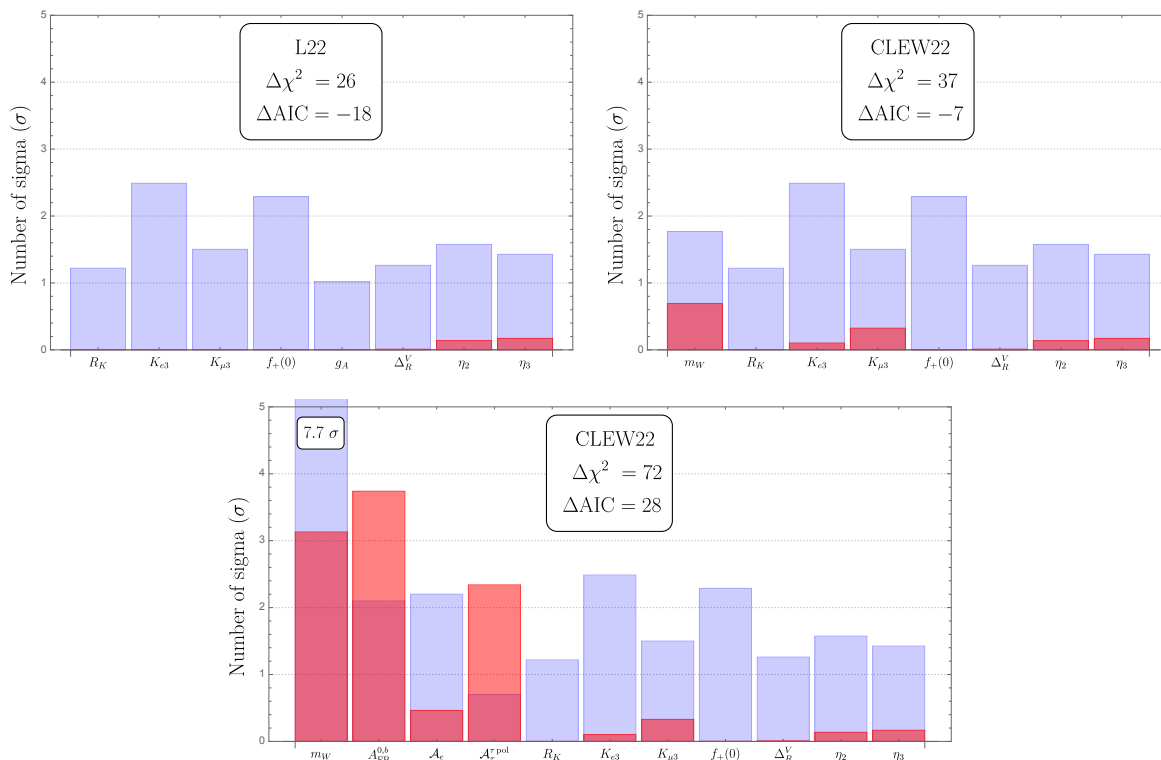

Figure 10. Same as figure 6, for three different SMEFT fits involving the 22 operators in the right panel of table 2. Left: L22 fit. Right: CLEW22 *without* CDF m_W. Bottom: CLEW22 *including* CDF m_W.

The role of CDF. In this section, we focused on the CAA and found that right-handed currents have the best performance. The possible advantage of including additional operators is that they can potentially account for the CDF measurement of m_W. We already saw this in the fits with left-handed operators which slightly improved the description of the EWPO. While the inclusion of the CDF result is the main topic of the next section, we can already see what happens in the context of the CLEW22 fit. As shown in the bottom panel of figure 10, it is possible to reduce the tension in m_W to 3σ. However, the 22 operators discussed here can only do so by introducing a large tension with other EWPO. Although $\Delta\text{AIC} = 28$ is still very good, $A_{\text{FB}}^{0,b}$ obtained a 4σ discrepancy, which implies that the fit is not optimal. In the next section, we transition to a scenario that does not rely on flavor assumptions, encompassing all 37 coefficients in table 2. Our aim is to determine whether we can more accurately represent both the CAA and m_W at the same time.

7.5 Intermediate conclusions

We have investigated the CAA by including all SMEFT operators that contribute to low-energy CC observables, without making use of flavor assumptions. Although there are 22 such operators, a detailed study of various fits indicates that many operators do not play a big role in the CAA. We summarize the performance of the fits in table 8.

The best fit (with the highest ΔAIC) is given by just including the two RH CC operators. The next best fit is obtained by adding LH vertex corrections, which can slightly improve

	L		LEW		CLEW	
	$\Delta\chi^2$	ΔAIC	$\Delta\chi^2$	ΔAIC	$\Delta\chi^2$	ΔAIC
2(RH)	22	18	22	18	22	18
6(SPS)	13	0	13	0	13	0
8(RS)	25	9	25	9	25	9
6(LH)	12	0	12	0	7	-5
12(LH)	12	-12	16	-8	22	-2
7(V)	23	9	27	13	27	13
22(All)	26	-18	31	-13	37	-7

Table 8. $\Delta\chi^2$ and ΔAIC values with respect to the SM for various SMEFT scenarios and sets of observables.

the EWPO but at the price of additional parameters. A similar quality of fit is obtained by combining the RH CC operators with scalar/pseudoscalar four-fermion operators. Other possibilities that do not include RH CC lead to an AIC that is comparable to or worse than that of the SM.

Incorporating the CDF measurement of m_W results in a suboptimal performance for CLEW22. Although it has a positive ΔAIC, it keeps tension in m_W at 3σ and severely compromises other observables. To convincingly address both anomalies at the same time, we must include more operators (the left panel of table 2). This will be discussed in the following section.

8 A flavor-independent global analysis

In the final analysis, we would like to investigate the interplay of the CDF measurement of m_W and the CAA. We will expand our set of operators to include the Wilson coefficients listed in the left panel of table 2. The fit incorporates 37 Wilson coefficients, the SM parameter λ, as well as a collection of matrix elements and parameters characterizing theoretical uncertainties.

We present the predicted observables at the best-fit point of the global fit CLEW37 in figure 11. CLEW37 successfully removes tension in the CDF W mass and the CAA, as well as several other observables. We obtain $\Delta\chi^2 = 103$ and ΔAIC $= 29$, indicating a significant improvement over the SM, comparable to that of the CLEW22 fit. The best-fit results show that all Wilson coefficients are consistent with zero within about 2σ (see the Supplemental Material for the central values, uncertainties, and correlations). However, as in the CLEW22 fit, there are several eigenvectors that are nonzero with significance $\gtrsim 3\sigma$. Neglecting the contributions to the normalized eigenvectors that are less than 0.3, we find

$$0.51\,C_{ST} + 0.33\,C_{Hl}^{(3)}{}_{22} + 0.45\,C_{ledq}{}_{2222} - 0.40\,\bar{C}_{lequ}^{(1)}{}_{2211} - 0.34\,C_{ll}{}_{2112} = -0.0016 \times (3.7 \pm 1)\,\text{TeV}^{-2},$$

$$0.41\,C_{ST} - 0.47\,C_{Hl}^{(3)}{}_{22} + 0.42\,C_{ll}{}_{2112} = -0.0030 \times (6.5 \pm 1)\,\text{TeV}^{-2},$$

$$-0.83\,C_{He}{}_{11} - 0.34\,C_{Hl}^{(1)}{}_{11} - 0.31\,C_{Hl}^{(3)}{}_{11} = 0.0093 \times (3 \pm 1)\,\text{TeV}^{-2}. \qquad (8.1)$$
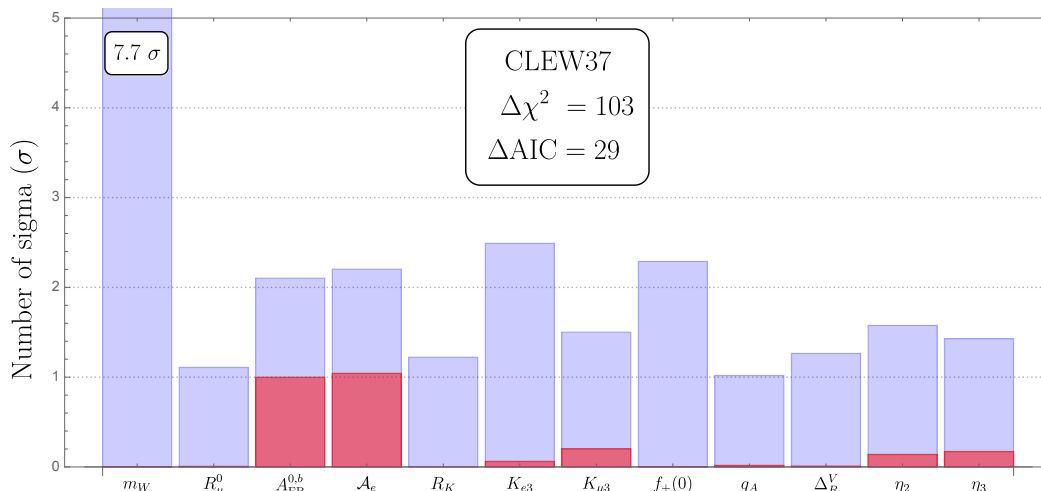

– 34 –

Figure 11. Same as figure 6, for all of the 37 operators to the CLEW data set.

The significant improvement in ΔAIC is mainly due to the large tension of the CDF W mass. Fitting CLEW37 with the PDG average of m_W instead, we obtain $\Delta\chi^2 = 47$ and ΔAIC $= -27$, a performance worse than the SM. In this case, there are too many operators that do not contribute significantly to $\Delta\chi^2$.

Even with the CDF m_W, the inclusion of all 37 operators is inefficient, resulting in overfitting and a suboptimal ΔAIC. In the next section, we perform a systematic analysis of various scenarios to pinpoint the SMEFT operators that are most important in addressing the CAA and the m_W anomaly.

8.1 Finding the optimal fit

Section 7 focused on the CAA and we investigated scenarios with various subsets of SMEFT operators. In these cases, we handpicked the operators that were likely to provide the most efficient way to account for the apparent violation of the CKM unitarity. Now that we are also including the W mass anomaly, this dissection by hand is complicated by the large number of possible subsets. Therefore, we implement a more systematic approach to find the optimal fit.

Recall that we define a 'model' as the SMEFT Lagrangian with a specific subset of Wilson coefficients turned on. For example, we found that models with C_{Hud} tend to give the highest ΔAIC and thus provide a more likely explanation of the CAA. Although we have explored a fair number of models, they represent only a fraction of the potential combinations of SMEFT operators. However, evaluating every combination of the 37 operators would amount to $2^{37} = \mathcal{O}(10^{11})$ fits, an impractical endeavor. We therefore group the operators into ten categories that are summarized in table 9. Our underlying theoretical motivation is that a particular BSM scenario is unlikely to produce just one quark/lepton flavor component in a specific category. We therefore turn on, or off, all Wilson coefficients within a certain category simultaneously. This assumption will be partially relaxed in section 8.4. For now, we consider all possible combinations of these ten categories, resulting in $2^{10} = 1024$ models.

Category	Operators	Description	# of Ops.	W_θ^{PDG}	W_θ^{CDF}
I.	C_{ST}	Oblique corrections	1	0.55	1.00
II.	C_{Hud}	RH charged currents	2	0.99	0.96
III.	$C_{Hl}^{(1)}$ $C_{Hl}^{(3)}$	LH lepton vertices	6	0.01	0.11
IV.	C_{He}	RH lepton vertices	3	0.09	0.42
V.	$C_{Hq}^{(u)}$ $C_{Hq}^{(d)}$	LH quark vertices	5	0.03	0.13
VI.	C_{Hu} C_{Hd}	RH quark vertices	5	0.06	0.32
VII.	C_{ll}	Lepton 4-fermion	1	0.37	0.87
VIII.	$C_{lq}^{(u)}$ $C_{lq}^{(d)}$	Semileptonic 4-fermion	6	0.03	0.03
IX.	C_{ledq} $C_{lequ}^{(1)}$	Scalar 4-fermion	6	0.02	0.04
X.	$C_{lequ}^{(3)}$	Tensor 4-fermion	2	0.13	0.13

Table 9. We divide the 37 operators identified in the left panel of table 2 into ten categories. In the third column, each category is described by the type of operators within it, which are listed in the second column. The fourth column counts how many operators among the 37 are included in each category. The fifth column gives the total weights of all models that contain the corresponding category, as described in eq. (4.8). The sixth column repeats this using the CDF m_W.

8.2 PDG value of m_W

We start by performing these fits with the PDG value of m_W. We show the resulting ΔAIC as a function of the number of parameters for all 1024 models in figure 12. The figure shows that the models can be divided into roughly three 'branches':

1. Models that include the right-handed current coefficients C_{Hud} (green triangle)

2. Models that include both C_{ST} and C_{ll}, but not C_{Hud} (orange diamond)

3. Rest of the models (blue circle)

The best-performing models fall into the first category which includes right-handed charged currents. In fact, the optimal model contains λ, $[C_{Hud}]_{11}$, $[C_{Hud}]_{12}$, and C_{ST} as fit parameters and has ΔAIC = 19. The best-fit results are given by

$$C_{Hud}_{11} = (-0.030 \pm 0.008)\,\text{TeV}^{-2}\,,$$

$$C_{Hud}_{12} = (-0.040 \pm 0.011)\,\text{TeV}^{-2}\,,$$

$$C_{ST} = (-0.0038 \pm 0.0022)\,\text{TeV}^{-2}\,. \tag{8.2}$$

The values for C_{Hud} are the same as those found in the L2(RH) discussed in the previous section (see table 6). The nonzero value of C_{ST} accounts for the slight discrepancy in m_W that is present even when the CDF measurement is excluded. In fact, the observables and matrix elements most improved in this model closely resemble those of L2(RH), which are shown in the left panel of figure 6. In addition, the tension in m_W is reduced from approximately 2σ to less than 1σ.
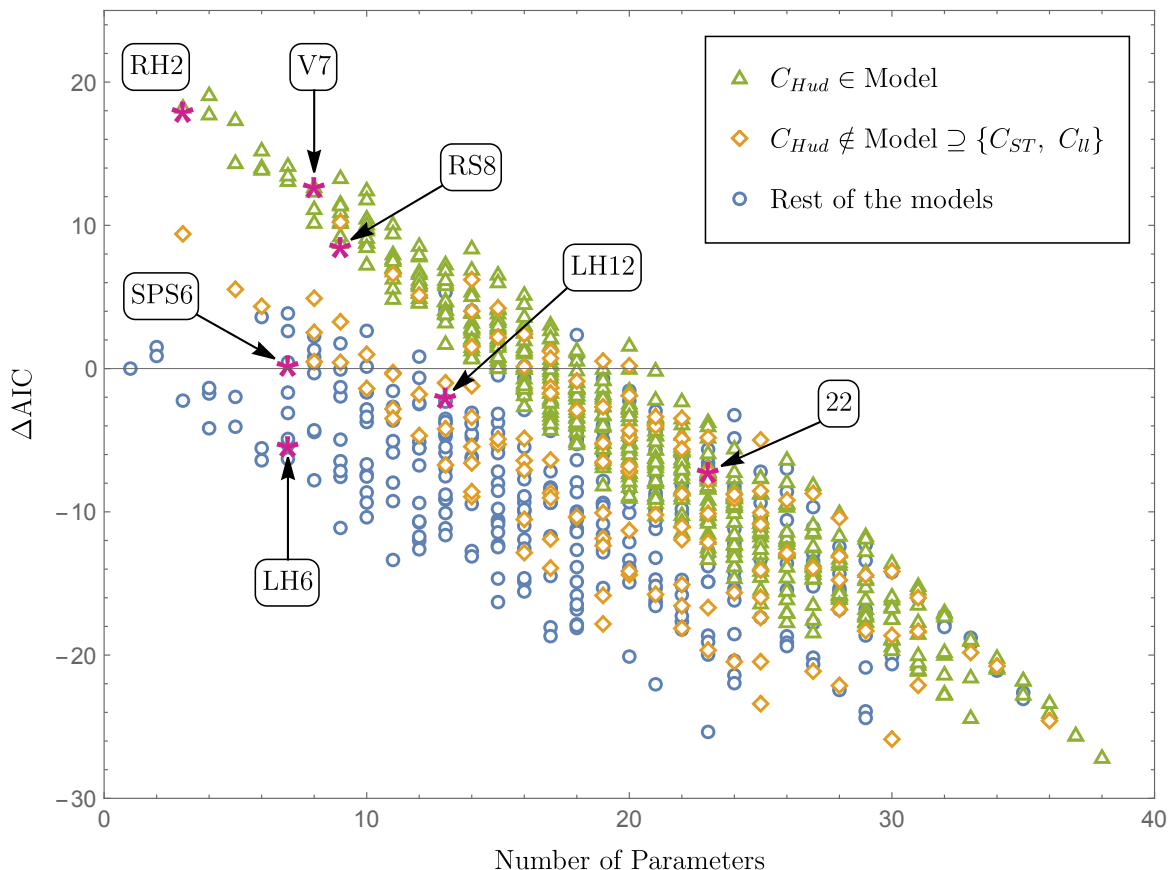

Figure 12. *Excluding* the CDF m_W, we plot ΔAIC for the 1024 models with respect to their number of parameters. Models containing the category C_{Hud} are marked with green triangles. Orange diamonds represent those that contain both C_{ST} and C_{ll}, but not C_{Hud}. The rest of the models are denoted by blue circles. The purple stars denote the seven models we have analyzed in section 7 and are labeled by their acronyms.

The second-best model (with ΔAIC = 18) is nothing more than L2(RH), while the third-best model includes C_{Hud} and C_{ll}. The two models L7 (V) and L8 (RS) that we studied in section 7 also fall into this family, with the additional parameters causing a penalty in AIC.

Of the 41 models selected for their performance, where their values of ΔAIC are within 10 units below the best model, only two exclude the right-handed operator, while they include both C_{ll} and C_{ST} (marked by orange diamonds in figure 12). A three-parameter fit with only λ, C_{ll} and C_{ST} has a ΔAIC = 9, with both C_{ll} and C_{ST} nonzero at more than 3σ,

$$C_{ll} = (-0.013 \pm 0.004) \text{ TeV}^{-2}, \qquad C_{ST} = -(0.0083 \pm 0.0026) \text{ TeV}^{-2}. \tag{8.3}$$

The combination of C_{ll} and C_{ST} performs significantly better than having just one of the two. C_{ll} can improve low-energy observables at the cost of a poorer description of several EWPO. Similarly, C_{ST} can improve m_W a bit but worsens other observables. However, the combination performs better across the chart.

The nine-parameter model with C_{ST}, C_{ll}, and six scalar/pseudoscalar operators yields ΔAIC = 10. It performs better than the L6(SPS) model, which only contains the scalar/pseudoscalar operators and has a ΔAIC = 1, shown in figure 12 by a purple star right
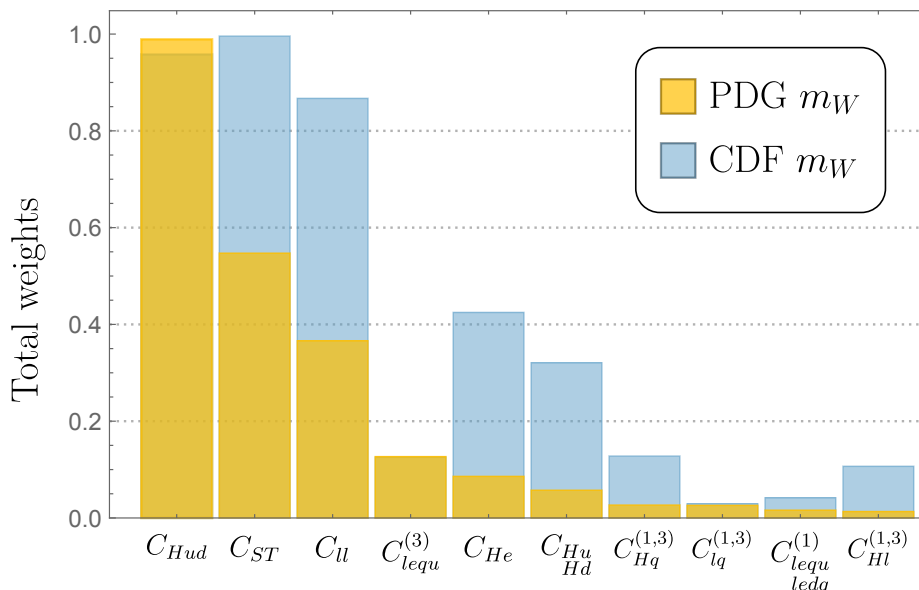

Figure 13. Model-averaged weights for each category of operators, as defined in eq. (4.8). Yellow bars: PDG world average of m_W. Blue bars: CDF measurement of m_W.

above the SM line ($\Delta \text{AIC} = 0$). The remaining three models studied in section 7, also marked by purple stars, all have a worse AIC than the SM and thus are disfavored.

Among all models that contain neither C_{Hud} nor the pair $\{C_{ST}, C_{ll}\}$ (marked by blue circles), the best performance, $\Delta \text{AIC} = 5$, is achieved by a model consisting of 13 parameters, including C_{ST}, the left-handed quark vertices $C_{Hq}^{(u)}$ and $C_{Hq}^{(d)}$, and the scalar/pseudoscalar four-fermion operators C_{ledq} and $C_{lequ}^{(1)}$.

Using the sum of weights W_θ to assess the importance of a given operator, the yellow bars in figure 13 show that C_{Hud} is the most important[4] with $W = 0.99$. C_{ST} and C_{ll} are the second and third most important with $W = 0.55$ and 0.33, respectively, followed by the tensor operator $C_{lequ}^{(3)}$ and the right-handed leptonic vertex corrections C_{He}, with $W \sim 0.1$. All other operators have $W < 0.1$. Using eq. (4.9), we can provide the model-averaged best-fit values of the most important Wilson coefficients,

$$C_{Hud}_{11} = -0.029 \pm 0.016 \text{ TeV}^{-2}, \qquad C_{Hud}_{12} = -0.039 \pm 0.014 \text{ TeV}^{-2},$$
$$C_{ST} = -0.0045 \pm 0.0032 \text{ TeV}^{-2}, \qquad C_{ll} = -0.001 \pm 0.012 \text{ TeV}^{-2}. \qquad (8.4)$$

Compared with eq. (8.2), we see that even after model averaging there is evidence for an up-strange RH current at the 2.7σ level, with σ defined in eq. (4.9). The evidence for an up-down RH current is diluted to roughly 2σ. C_{ST} deviates from zero by slightly more than 1σ, while C_{ll} is compatible with zero. The values in eq. (8.4) may provide guidance for model building.

8.3 CDF value of m_W

We now repeat our analysis including the CDF m_W. We plot ΔAIC as a function of the number of parameters for all 1024 fits in figure 14. Although it is harder to identify distinct

---

[4]A weight of 0.99 means that the 512 models that do not contain right-handed currents collectively carry only 1% of the weight as defined in eq. (4.8).
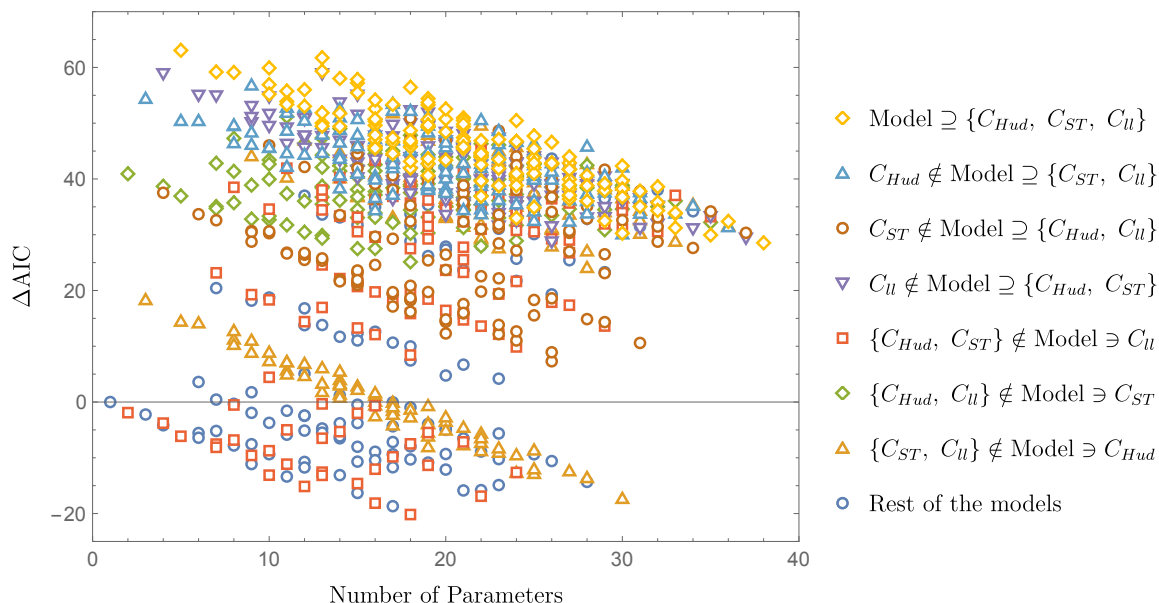

Figure 14. *Including* the CDF m_W, we plot ΔAIC for the 1024 models with respect to their corresponding number of parameters. The legend shows various categories of Wilson coefficients contained in the models, denoted by the corresponding markers.

'branches' compared with the PDG results in figure 12, the same Wilson coefficients appear in the highly performing models: C_{Hud}, C_{ST}, and C_{ll} (models that include these operators are denoted by yellow diamonds). In fact, the best model contains only these four operators with their best-fit values given by

$$
\underset{11}{C_{Hud}} = \ \ 0.025 \pm 0.024 \ \text{TeV}^{-2}, \qquad\qquad \underset{12}{C_{Hud}} = -0.033 \pm 0.011 \ \text{TeV}^{-2},
$$

$$
C_{ST} = -0.022 \pm 0.004 \ \text{TeV}^{-2}, \qquad\qquad \underset{2112}{C_{\ ll}} = -0.028 \pm 0.011 \ \text{TeV}^{-2}. \tag{8.5}
$$

This fit has a very high ΔAIC = 63. We show how it improves certain observables and matrix elements in the left panel of figure 15. In particular, the four operators can reduce the tension in m_W to 1.5σ and take care of the problems in kaon and $0^+ \to 0^+$ decays. Compared to the PDG results in eqs. (8.2) and (8.4), the CDF fit prefers to use C_{ll} to reconcile m_W. As the same operator affects β decay observables as well, this leads to a modified (and positive) value for $[C_{Hud}]_{11}$. However, it increases the tension in forward-backward asymmetry of the bottom quark, $A_{\text{FB}}^{0,b}$. We also see this in figure 10 associated with the CLEW22 analysis.

Interestingly, the second-best model contains 12 independent Wilson coefficients. In addition to those four in the best model, it includes three RH lepton vertices (C_{He}) and five RH quark vertices (C_{Hu} and C_{Hd}). Despite the inclusion of eight additional parameters, it achieves a similar ΔAIC = 62. The best-fit values are given in the third column of table 10, and the improvements in observables are illustrated on the right of figure 15. Compared to those of the best-fit model on the left, we see that the high tension in $A_{\text{FB}}^{0,b}$ disappears due to the nonzero values of $[C_{He}]_{11}$ and $[C_{Hd}]_{33}$, which both have a significance level of 2σ. This effect can be understood from eqs. (6.8) and (6.10). Apart from the RH currents, this

Table 10. Best-fit and 1σ ranges for the best model ($\Delta\text{AIC} = 63$), the next-to-best model ($\Delta\text{AIC} = 62$) and after model averaging, including the CDF m_W. Wilson coefficients are given in units of TeV^{-2}.

model somewhat resembles the $\text{U}(3)^5$ scenario we studied in section 6 with $\Delta\text{AIC} = 57$. In fact, the best-fit values are not inconsistent with $\text{U}(3)^5$, except for the appearance of C_{Hud}. Specifically, all $[C_{He}]_{ii}$ have a comparable central value.

The best model that does not contain all three categories of C_{Hud}, C_{ST} and C_{ll} has a $\Delta\text{AIC} = 59$. It only contains C_{Hud} and C_{ST}, corresponding to the leftmost purple triangle in figure 14. The best model without C_{Hud} has $\Delta\text{AIC} = 56$. It contains C_{ST}, C_{ll}, and six scalar four-fermion operators (C_{ledq} and $C_{lequ}^{(1)}$).

Models without C_{ST} are notably inferior, lagging more than 10 units in ΔAIC behind the best model, making them strongly disfavored. Models that do not contain any of the operators in the categories C_{Hud}, C_{ST}, or C_{ll} perform even worse, as marked by the blue circles in figure 14.

We conclude that the most important operators are given by C_{Hud}, C_{ST}, and C_{ll}. Operators C_{He}, C_{Hu}, and C_{Hd}, while slightly less important, remain relevant. This is

	Model 1	Model 2	Model 3

Table 11. Best-fit and 1σ ranges for the top three models discussed in section 8.4, all with $\Delta\text{AIC} \simeq 68$. Wilson coefficients are given in units of TeV^{-2}.

reflected in the model-averaged weights that are illustrated by the blue bars in figure 13. The model-averaged best-fit values of these coefficients are given in the fourth column of table 10. The model-averaged results indicate a preference for nonzero values of C_{ST} and, to a lesser extent, C_{ll}, $[C_{Hud}]_{12}$, $[C_{He}]_{11}$, $[C_{He}]_{33}$, and $[C_{Hd}]_{33}$. It is essentially a mixture of the best and second-best models.

8.4 Opening the categories

As mentioned in section 8.3, the second-best model with the CDF m_W has a ΔAIC very close to that of the best model. In addition to the four operators that appear in the best model ($[C_{Hud}]_{11,12}$, C_{ST}, and C_{ll}), eight operators are included in the categories of right-handed lepton and quark vertices, namely $[C_{He}]_{11,22,33}$, $[C_{Hu}]_{11,22}$, and $[C_{Hd}]_{11,22,33}$. This leads to an improvement in χ^2 by 15. It is possible that not all of the eight are necessary. To investigate this, we open up the categories and consider all combinations of them, resulting in $2^8 = 256$ models, while keeping $[C_{Hud}]_{11,12}$, C_{ST}, and C_{ll} in every model by default.

In doing so, we actually find three models that perform better than our previous best model, all with $\Delta\text{AIC} \simeq 68$, see table 11 for details. None of these three models contains C_{Hu}. By including both C_{Hu} and C_{Hd} in category V, as defined in table 9, we may have inadvertently introduced unnecessary complexity into some fits. Instead, the best three models all contain $[C_{He}]_{11}$ and $[C_{Hd}]_{33}$, which confirms our observation in section 8.3, that these operators help reduce the tension in $A_{\text{FB}}^{0,b}$. Based on this analysis, the most important SMEFT operators are $[C_{Hud}]_{11,12}$, C_{ST}, C_{ll}, $[C_{He}]_{11}$, and $[C_{Hd}]_{33}$.

9 Falsifying explanations of the Cabibbo anomaly

In section 8.1, we concluded that the preferred explanation for CAA within SMEFT involves nonzero values of the RH CC coefficients $[C_{Hud}]_{11}$ and $[C_{Hud}]_{12}$. The CAA and CDF m_W can be explained by $[C_{Hud}]_{12}$, C_{ST}, and C_{ll} that deviate from zero by more than 2.5σ. In this section we discuss how these Wilson coefficient could lead to signals in other observables, which are currently less sensitive but may gain in sensitivity thanks to theoretical and

experimental developments in the near future. Some of these observables, such as nucleon axial coupling g_A discussed in section 9.1, only receive contributions from the operators appearing in table 1 at the tree level in SMEFT. In this case, the CLEW setup discussed in this paper could be easily extended to incorporate new results as soon as they appear. For other observables, such as $K \to \pi\pi$, $h \to \gamma\gamma$, or collider observables that are quadratic in the RH coefficients, the operators that contribute to the CAA and the m_W anomaly are only a subset of all possible SMEFT contributions. In these cases, a signal of the size predicted by the nonzero Wilson coefficients in section 8.1 would offer a tantalizing confirmation of the explanations identified so far. The absence of a signal would not necessarily rule out the CAA and m_W anomalies, but would imply correlations with additional operators not considered in our analysis, such as $\Delta S = 1$ four-quark operators or Higgs-gauge couplings, thus providing additional guidance to model building.

9.1 RH CC at low energy: g_A and the $\Delta I = 3/2$ $K \to \pi\pi$ amplitude

g_A. At low energy, the axial nucleon coupling g_A is uniquely sensitive to RH CC [49, 94]. The value extracted from neutron decay can be related to the axial coupling in pure QCD via

$$\frac{g_A}{g_V} = g_A^{\text{QCD}} \left(1 + \delta_{\text{RC}}^{g_A} - v^2 \frac{[C_{Hud}]_{11}}{V_{ud}}\right), \tag{9.1}$$

where $\delta_{\text{RC}}^{g_A}$ denotes radiative corrections to the ratio of the axial and vector couplings. A RH coupling of the u and d quarks to the W boson of the size necessary to explain the CAA (as, for example, in eq. (8.4)) would shift g_A by about 0.2%. Eq. (9.1) can thus provide a sensitive test of RH CC if the experimental value of g_A/g_V, g_A in pure QCD and the radiative corrections to g_A are all controlled at the permille level. g_A/g_V is currently measured with 0.1% precision [3]

$$\frac{g_A}{g_V} = 1.2754 \pm 0.0013, \tag{9.2}$$

where the error is inflated by a scale factor of 2.7,[5] due to a discrepancy between different experimental results. The best measurement from PERKEO-III [95] has an even smaller relative uncertainty of $0.4 \cdot 10^{-3}$. The FLAG average of g_A^{QCD} [12] is

$$g_A^{\text{QCD}} = 1.246 \pm 0.028, \qquad N_f = 2 + 1 + 1, \tag{9.3}$$

$$g_A^{\text{QCD}} = 1.248 \pm 0.023, \qquad N_f = 2 + 1, \tag{9.4}$$

with about 2% error. The result of the CalLat collaboration reaches a subpercent uncertainty [96, 97]

$$g_A^{\text{QCD}} = 1.2711 \pm 0.0124, \tag{9.5}$$

with prospects of reaching 0.5% uncertainty in the near term and possible 0.2% in the exascale computing era [96, 97]. The final theoretical input is the radiative correction $\delta_{\text{RC}}^{g_A}$. Dispersive evaluations of the vector and axial $W\gamma$ box contributions to $\delta_{\text{RC}}^{g_A}$ estimated that the correction

---

[5]Our analysis in the previous sections instead follows the strategy and experimental input used in ref. [51]. This effectively leads to a value of g_A that is very similar to the one obtained in ref. [3], apart from the mentioned scale factor.

is well below 10^{-3} [8, 98]. In addition, g_A gets contributions from hard photon exchanges between hadrons ('three-point function'). These have been estimated to be at the level of a few percent using chiral perturbation theory (χPT) techniques [99], but are affected by large uncertainties. Ref. [99] quoted

$$\delta_{\mathrm{RC}}^{g_A} \in \{0.014, 0.026\}, \tag{9.6}$$

with the range determined by an unknown combination of electromagnetic low-energy constants, which was estimated by varying the renormalization scale in LO χPT loops, and by the uncertainties in the couplings of the axial current to two nucleons and a pion that affect NLO corrections to $\delta_{\mathrm{RC}}^{g_A}$. For g_A to provide a stringent test of the CAA, it is therefore necessary to improve the theoretical calculations of both g_A^{QCD} and $\delta_{\mathrm{RC}}^{g_A}$.

$K \to \pi\pi$. In addition to semileptonic processes, C_{Hud} also induces nonleptonic four-fermion operators. At low energy, one finds [100]

$$\mathcal{L}_{\mathrm{LEFT}} = -\sum_{a=1}^{2} \left(C_{aLR}^{ij\,lm} \mathcal{O}_{aLR}^{ij\,lm} + C_{aLR}^{ij\,lm\,*} (\mathcal{O}_{aLR}^{ij\,lm})^\dagger \right), \tag{9.7}$$

with the operators given by

$$\mathcal{O}_{1LR}^{ij\,lm} = \bar{d}^m \gamma^\mu P_L u^l \, \bar{u}^i \gamma_\mu P_R d^j, \qquad \mathcal{O}_{2LR}^{ij\,lm} = \bar{d}_\alpha^m \gamma^\mu P_L u_\beta^l \, \bar{u}_\beta^i \gamma_\mu P_R d_\alpha^j, \tag{9.8}$$

where α, β are color indices. Taking into account the QCD renormalization group evolution, the matching coefficients at low energy are given by

$$C_{1LR}^{ijlm}(\mu = 3\,\mathrm{GeV}) = 0.9 V_{lm}^* \, [C_{Hud}]_{ij}, \qquad C_{2LR}^{ijlm}(\mu = 3\,\mathrm{GeV}) = 0.4 V_{lm}^* \, [C_{Hud}]_{ij}. \tag{9.9}$$

The imaginary part of the Wilson coefficients in eq. (9.8) contributes to electric dipole moments (EDM) and to CP violation in mesonic decays. As a result, the imaginary part of $[C_{Hud}]_{11}$ and $[C_{Hud}]_{12}$ are strongly constrained, as we shall see below. The real part of the $\Delta S = 1$ operators affects the decay $K \to \pi\pi$. In particular, the amplitude A_2 for the decay into two pions with isospin $I = 2$ is suppressed in the SM and is therefore particularly sensitive to BSM corrections. The RH CC corrections to A_2 can be expressed as [100]

$$A_2 = A_2^{\mathrm{SM}} + \frac{F_0}{2\sqrt{6}} \left[(C_{1LR}^{udus} - C_{1LR}^{usud\,*}) \mathcal{A}_{1\,LR} + (C_{2LR}^{udus} - C_{2LR}^{usud\,*}) \mathcal{A}_{2\,LR} \right]. \tag{9.10}$$

The low-energy constants (LECs) $\mathcal{A}_{1\,LR}$ and $\mathcal{A}_{2\,LR}$ can be extracted from Lattice QCD calculations of ϵ'/ϵ [100–104]

$$\mathcal{A}_{1\,LR}(3\,\mathrm{GeV}) = \frac{1}{\sqrt{3}F_0} \langle (\pi\pi)_{I=2} | \mathcal{Q}_7 | K^0 \rangle + \mathcal{O}\left(m_K^2 \right) \simeq (2.2 \pm 0.13)\,\mathrm{GeV}^2,$$

$$\mathcal{A}_{2\,LR}(3\,\mathrm{GeV}) = \frac{1}{\sqrt{3}F_0} \langle (\pi\pi)_{I=2} | \mathcal{Q}_8 | K^0 \rangle + \mathcal{O}\left(m_K^2 \right) \simeq (10.1 \pm 0.6)\,\mathrm{GeV}^2, \tag{9.11}$$

where $\mathcal{Q}_{7,8}$ denote electroweak penguin operators. With these values of the LECs, we find

$$\mathrm{Re}(A_2) = \mathrm{Re}(A_2^{\mathrm{SM}}) + \left[11 \cdot 10^{-8}\,\mathrm{GeV} \right] \mathrm{Re}\left(V_{us}^* \, [C_{Hud}]_{11} - V_{ud}^* \, [C_{Hud}]_{12} \right)\mathrm{TeV}^2, \tag{9.12}$$
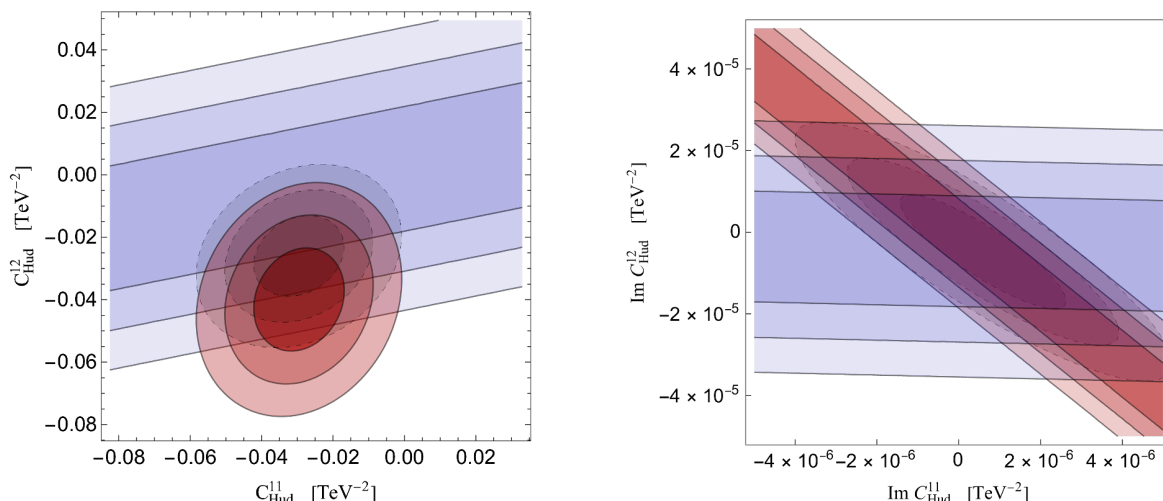

Figure 16. Left panel: the figure shows the L2(RH) scenario with the fit to L observables shown in red, while the constraint from A_2 is shown in blue. The combination of the two is depicted by dashed black lines. Right panel: the constraints from EDMs (red) and $\varepsilon'/\varepsilon_K$ (blue), as well as their combination (black, dashed), on the imaginary parts of the C_{Hud} couplings.

where $\mathrm{Re}(A_2) = 1.479(4) \cdot 10^{-8}$ GeV [3]. Due to the chiral enhancement of the LR operators, the suppression of the SM amplitude, and a further enhancement by V_{us}^{-1}, the values of $[C_{Hud}]_{12}$ that can explain the CAA can provide a positive $\sim 30\%$ correction to $\mathrm{Re}(A_2)$. As in the case of g_A, the sensitivity of $K \to \pi\pi$ to new physics is limited by the theoretical prediction for the SM value. The RBC/UKQCD collaboration [102, 103] reported

$$\mathrm{Re}(A_2^{\mathrm{SM}}) = 1.50(4)_{\mathrm{stat}}(14)_{\mathrm{syst}} \times 10^{-8}\,\mathrm{GeV}. \tag{9.13}$$

In figure 16 we repeat the L2(RH) fit, including $K \to \pi\pi$ with the assumption that C_{Hud} is the only source of $\Delta S = 1$ operators. The red ellipses are the results of the fit in section 7, the constraint from A_2 is shown by the blue bands, and the black ellipses denote the joint fit. We can see that the regions preferred by the fits to β and kaon decays and the constraints from A_2 are compatible at the 1σ level. The joint fit gives

$$[C_{Hud}]_{11} = -0.030 \pm 0.0084\,, \qquad [C_{Hud}]_{12} = -0.026 \pm 0.0085\,. \tag{9.14}$$

The addition of A_2 to the fit currently somewhat shifts the best fit point of the L2(RH) scenario discussed in section 7 (see table 6). The preferred value of $[C_{Hud}]_{12}$ is most affected by A_2, although the shift is not greater than $\sim 1\sigma$. Future improvements in the lattice determination of A_2^{SM} could provide a more sensitive probe of the RH couplings.

EDMs and ϵ'/ϵ. The phases of the RH CC coefficients $[C_{Hud}]_{11}$ and $[C_{Hud}]_{12}$ induce tree-level corrections to the neutron EDM, to atomic EDMs, and to direct CP-violation in kaon decays (ϵ'/ϵ), through the non-leptonic operators $\mathcal{O}_{1\,LR}$ and $\mathcal{O}_{2\,LR}$. These contributions were studied in refs. [100, 105], and lead to very strong constraints, shown in the right panel of figure 16. The constraints on the imaginary parts of $[C_{Hud}]_{11}$ and $[C_{Hud}]_{12}$ can be naively translated into scales in the 250 to 500 TeV range, much larger than the scales associated with the real part.

Similarly, the CP-violating partner of Q_{HWB} contributes to the electron EDM at one loop. In a single coupling scenario, its coefficient is restricted to below $3 \times 10^{-6}\,\mathrm{TeV}^{-2}$ (95% CL) [106, 107]. While the combination of right-handed charged currents and oblique corrections provides an attractive explanation for the CAA and tensions in EWPO, when matching to concrete UV-complete models, some care must be taken to ensure that their phases are aligned with the SM.

9.2 Collider signatures

C_{HWB} and C_{HD} are degenerate in EWPO. The degeneracy is broken in Higgs observables, WZ, and WW production data [45, 70, 108, 109]. With new and more precise data from the LHC, Higgs properties and diboson production are becoming highly competitive with EWPO [70]. For example, a SMEFT fit to $H \to \gamma\gamma$ data [110] yields, in the single coupling assumption,

$$C_{HWB} = 0.0020^{+0.0044}_{-0.0042}\,\mathrm{TeV}^{-2}, \qquad C_{HD} = -0.21^{+0.42}_{-0.44}\,\mathrm{TeV}^{-2}. \tag{9.15}$$

These can be translated values of C_{ST}

$$C_{ST}|_{HWB} = 0.0018^{+0.0040}_{-0.0038}\,\mathrm{TeV}^{-2}, \qquad C_{ST}|_{HD} = -0.087^{+0.17}_{-0.18}\,\mathrm{TeV}^{-2}. \tag{9.16}$$

The relatively weak sensitivity to C_{HD} implies that, even under the single coupling assumption, $h \to \gamma\gamma$ is not sufficient to exclude the C_{ST} explanation for m_W. Eq. (9.16) however illustrates the potential of Higgs measurements to provide constraints that are orthogonal to EWPO. In addition to C_{HWB} and C_{HD}, the quark bilinear operators in table 2 give contributions to Higgs and diboson production that are enhanced with respect to the SM and grow with energy. In particular, $C_{Hq}^{(3)}$ contributes to the production of HW and WZ, $C_{Hq}^{(1)}$, $C_{Hq}^{(3)}$, C_{Hu} and C_{Hd} to HZ and WW. Going forward, it will be important to perform combined fits to EWPO, Higgs data, and diboson production at the LHC [45, 70, 108, 109]. It will be desirable to minimize the flavor assumptions and to combine these fits with Drell-Yan and low-energy data, in particular β decay and parity-violating electron scattering data.

Higgs and diboson data are also sensitive to the right-handed current operator C_{Hud}, although in quadratic order. C_{Hud} is not strongly constrained by the charged-current Drell-Yan processes because it gives rise to corrections with the same energy dependence as the SM background. On the other hand, C_{Hud} gives large corrections to WH and WZ associated production. In the former case, contact interactions between two quarks, one Higgs, and a W induce corrections to WH that are enhanced by s/m_W^2 compared to the SM. In WZ production, the presence of a right-handed current affects a cancellation between the t- and s-channel diagrams in the SM and also leads to corrections that increase in energy as s/m_W^2.

Corrections to the signal strengths of WH production were discussed in refs. [78, 105] and can be written as

$$\mu_{WH} = \frac{\sigma_{W^+H} + \sigma_{W^-H}}{\sigma_{W^+H}^{\mathrm{SM}} + \sigma_{W^-H}^{\mathrm{SM}}} = 1 + \sum_{ij} a_{ij} \left| v^2 C_{Hud_{ij}} \right|^2. \tag{9.17}$$

At NLO in QCD the coefficients a_{ij} are [105]

$$a_{11}(13\,\text{TeV}) = 1.6(1) \cdot 10^2\,, \qquad a_{11}(14\,\text{TeV}) = 1.7(1) \cdot 10^2\,,$$

$$a_{12}(13\,\text{TeV}) = 0.9(2) \cdot 10^2\,, \qquad a_{12}(14\,\text{TeV}) = 1.0(1) \cdot 10^2\,, \tag{9.18}$$

where the error comes from PDF and scale uncertainties. The latest results from the ATLAS and CMS collaborations are [111, 112]

$$\mu_{WH}(13\,\text{TeV})|_{\text{ATLAS}} = 1.2 \pm 0.2\,, \qquad \mu_{WH}(13\,\text{TeV})|_{\text{CMS}} = 1.4 \pm 0.3\,, \tag{9.19}$$

leading to

$$|[C_{Hud}]_{11}| < 0.95\ \text{TeV}^{-2}\,, \qquad |[C_{Hud}]_{12}| < 1.3\ \text{TeV}^{-2}\,. \tag{9.20}$$

These limits are about one order of magnitude too weak to constrain the region preferred by the CAA in eq. (8.4). As the scaling is quadratic in the SMEFT coefficients, measurements of the signal strength alone will not be sufficient to competitively constrain C_{Hud}. However, the enhancement of the SMEFT corrections is more pronounced at high Higgs or W transverse momentum as well as large HW invariant mass, so that dedicated high p_T measurements could further constrain right-handed operators [78, 105].

For WZ, we calculated the cross section by extending the POWHEG implementation of WZ production in the SM [113] to right-handed W couplings. Corrections to the inclusive cross section are a factor of ten smaller compared to WH. For example, at 13 TeV

$$\mu_{WZ} = \frac{\sigma_{W^+Z} + \sigma_{W^-Z}}{\sigma_{W^+Z}^{\text{SM}} + \sigma_{W^-Z}^{\text{SM}}} = 1 + 19\left[v^2 C_{Hud}\right]_{11}^2 + 9\left[v^2 C_{Hud}\right]_{12}^2\,. \tag{9.21}$$

However, the absolute cross section is larger, and there exist precise measurements of the total cross section and differential measurements at high transverse momentum or invariant mass [114], where the contribution of RH CCs is enhanced. At the High-Luminosity LHC (HL-LHC), couplings of the size $[C_{Hud}]_{12} \sim 0.1\,\text{TeV}^{-2}$, which are relevant to the Cabibbo anomaly, will generate hundreds of events with $M(WZ) \gtrsim 1\,\text{TeV}$, so that at least part of the parameter space identified in section 8.1 will be probed. As RH CCs affect Higgs observables and diboson production at $\mathcal{O}(\Lambda^{-4})$, the derivation of consistent bounds requires the inclusion of genuine dimension-eight operators [115]. Should deviations from the SM be observed, differential observables such as angular distributions could offer valuable insights into the chiral structure of the SMEFT operators [78, 105].

10 Conclusions

In this work, we performed a model-independent SMEFT global analysis to investigate potential BSM explanations of the Cabibbo Angle Anomaly. The SMEFT framework offers a systematic approach to analyze experimental data globally, but its practical implementation is challenging due to the vast number of dimension-six operators and the corresponding effective couplings. To manage this, flavor assumptions are often invoked to simplify the analysis. However, such assumptions can reintroduce model dependence and miss certain BSM explanations.

To avoid this, as discussed in section 3, we embrace a 'flavor-assumption-independent' analysis, which implements an approximate decoupling of the global fit into flavor-conserving and flavor-changing sectors, corresponding to an approximate factorization of the likelihood function. Therefore, we expect that the results we obtain in the flavor-conserving sector would not be significantly changed in a truly global analysis that explicitly includes all 'cross talk' generated by Wilson coefficients that contribute to multiple classes of observables (for example, the set of observables considered here and FCNCs).

Observables across three key data sets (dubbed CLEW) that are relevant to the CAA were analyzed: low-energy charged-current semileptonic processes (L), electroweak-precision observables (EW), and collider data of the Drell-Yan tails at the LHC (C). We performed fits by minimizing the χ^2 and used the Akaike Information Criterion (AIC) to determine the relative quality of the resulting fits. The AIC penalizes models for excessive complexity and ensures a balance between goodness of fit and simplicity when selecting models. Before considering the model-independent analysis outlined above, we first revisited a scenario that does make flavor assumptions, namely, a $U(3)^5$ scenario. We subsequently considered a case that includes all 22 operators contributing to the L observables (see the right panel of table 2), before finally moving to the global analysis with 37 Wilson coefficients (see the left panel of table 2). The salient features of our results can be summarized as follows:

- As discussed in section 6, in the $U(3)^5$ scenario it is impossible to separate the EWPO from both low- and high-energy CC observables because of their interdependence on similar operators and their comparable sensitivities to BSM physics. Focusing only on fitting to the EWPO can result in unacceptably large BSM effects in low-energy decay processes, which cannot be offset by semileptonic four-fermion operators without upsetting collider constraints. Therefore, a consistent analysis should include both sets of observables. The traditional set of EWPO as considered in the literature is no longer sufficient, and we advocate always considering the combination with low- and high-energy CC observables.

- For the intermediate flavor-symmetry-independent fit discussed in section 7, we explored the CAA without relying on flavor assumptions. The corresponding fit involves 22 potential Wilson coefficients, the results of which are provided in the Supplemental Material. Although initially considering all operators, it became evident that many play an inconsequential role in alleviating the CAA, motivating analyses involving subsets of Wilson coefficients. The optimal fit (based on the highest ΔAIC) involves only two RH CC operators. These SMEFT operators are strongly suppressed when minimal flavor violation is employed, illustrating the risk of flavor assumptions. Including LH vertex corrections can slightly improve the description of the EWPO, but results in a lower ΔAIC. Combining RH currents with scalar/pseudoscalar four-fermion operators offers a fit of similar quality. Other combinations without RH currents might reduce $\chi^2_{\min}$, but often lead to an AIC similar to or worse than that of the SM. The more general scenario involving 22 operators can address low-energy new physics phenomena such as the CAA. However, when including the CDF measurement of the W mass, the performance of CLEW22 is not optimal. Although it improves the AIC compared to

the SM, it does retain a 3σ tension in m_W and negatively impacts other observables. Addressing anomalies, such as the W mass, requires incorporating additional operators.

- The model-independent CLEW37 scenario is not only able to address the CAA, but can also successfully remove the tension due to the CDF W mass. Details of these fits are also provided in the Supplemental Material. The resulting AIC shows a clear improvement over the SM when including the CDF m_W, as discussed in section 8. On the other hand, if one uses the PDG value of m_W, this scenario leads to an AIC that is worse than the SM. The negative effect of the number of parameters outweighs the improvement in χ^2.

  Inspired by this, we conducted an analysis focusing on specific SMEFT 'models', each containing only a subset of the 37 Wilson coefficients. These subsets are systematically organized by the ten categories we outline in table 9. Overall, we considered 1024 such models and compared their quality with that of the SM. As summarized in figure 12, we find that scenarios involving RH CC operators have large ΔAICs, with the best model containing both C_{Hud} and C_{ST}. If one includes the CDF W mass, the best scenario contains one additional operator, namely, the purely leptonic interaction Q_{ll} (see figures 14 and 15 for details).

- While the model with C_{Hud}, C_{ST}, and C_{ll} has the optimal AIC, a more complicated model comes very close. This model contains SMEFT operators for the right-handed neutral currents C_{He}, C_{Hu}, and C_{Hd}. Although this brings eight additional fit parameters, and thus a severe penalty on the AIC, the fit improves several EWPO with respect to the optimal model (see figure 15). Furthermore, by opening the individual categories, we determined that the C_{Hu} coefficients are not essential. However, incorporating C_{He} and C_{Hd} does result in an enhancement.

- Finally, in section 9 we discuss possible observables that could falsify or verify the BSM explanations of the CAA, assuming the current deviation from CKM unitarity is confirmed. Given the previous discussion, we focus on the most likely explanations in terms of right-handed currents C_{Hud} and the oblique parameter C_{ST}. The former can be probed at low energies by the axial charge of the nucleon and the isospin $I = 2$ channel in $K \to \pi\pi$. In both cases, the required improvements would have to come from the theory side. At the high-energy frontier, promising probes include WH and WZ production. Future measurements at the HL-LHC are expected to be able to rule out at least part of the parameter space that is relevant to solutions of the CAA. Similarly, the HL-LHC will provide improved constraints on C_{ST} through measurements of $h \to \gamma\gamma$ and diboson production. Incorporating these observables into the global analysis would require more operators to participate in the CLEW framework. We leave them for future investigations.

- Our analysis can be extended in several directions. First, the SMEFT models discussed in section 8 depend on activating or deactivating operators in different categories. A more detailed analysis would allow each individual operator to be turned on or off by itself. The price to pay is a huge increase in the total number of models. Another

way to generalize our analysis is by including observables that currently have weaker sensitivity but could improve in the future, such as nonleptonic kaon decays, as well as Higgs and heavy-gauge boson production at high-energy colliders, as discussed in section 9. Finally, our analysis can be extended to include low-energy neutral current probes, such as measurements of parity violation in atoms or low-energy electron-proton scattering.

Throughout this paper, we have consciously avoided any reference to UV completions in an effort to stay as close to the EFT philosophy as possible. However, the CAA, regardless of whether we include the CDF m_W measurement or not, prefers nonzero values of C_{Hud} and C_{ST}. Interestingly, these effective operators are generated in models that feature vector-like quarks (VLQ). For example, TeV-scale VLQ in the same representation as left-handed SM quarks, $(\mathbf{3}, \mathbf{2}, \frac{1}{6})$, can address both the CAA (by generating C_{Hud} at tree level) and m_W (by generating C_{ST} at one-loop level) [35]. For more details on VLQ and CAA, see refs. [38, 116].

In summary, we have performed a detailed analysis of the Cabibbo Angle Anomaly and the W-boson mass anomaly in the framework of the Standard Model Effective Field Theory. We have presented best-fit values for Wilson coefficients that lead to the most optimal solutions of these anomalies. Our results provide clear targets for model building. We hope that the analysis method presented in this work will prove useful for scrutinizing other (future) anomalies and their most likely beyond-the-Standard-Model explanations.

Acknowledgments

A The Standard Model Effective Field Theory

We begin this appendix by recalling the main notation we adopt for the fermionic fields, the Higgs doublet and the covariant derivative. We denote by $l^T = (\nu_L, e_L)$ and $q^T = (u_L, d_L)$ the left-handed lepton and quark SU(2) doublets, while $u = u_R$, $d = d_R$, and $e = e_R$ are

the right-handed up-type, down-type, and charged-lepton fields. We use $p, r, s,$ and t for generation indices and work in a basis in which the electron and down-quark Yukawa matrices are diagonal. This implies that the fields $d_{L,R}, e_{L,R}$ correspond to the mass eigenstates, while for the up-type quarks we have $u_L = V^\dagger u_L^{\text{mass}}$, where V is the CKM matrix.

The Higgs doublet in the unitary gauge is given by

$$H = \text{U}(x) \begin{pmatrix} 0 \\ \frac{h(x)+v}{\sqrt{2}} \end{pmatrix}. \tag{A.1}$$

Here h is the Higgs field, $\text{U}(x)$ encodes the Goldstone modes, and v is the Higgs vacuum expectation value, which, in the absence of BSM effects, takes the value $v \simeq 246\,\text{GeV}$. We use the following convention for the covariant derivative,

$$D_\mu = \partial_\mu + i\,g_1 Y B_\mu + i\,g_2 W_\mu^a t^a + i g_3 G_\mu^A T^A, \tag{A.2}$$

where B_μ, W_μ^a, and G_μ^A (g_1, g_2, and g_3) are the gauge fields of U(1), SU(2), and SU(3)$_c$ (couplings). Furthermore, Y is the hypercharge, while t^a and T^A represent the generators of SU(2) and SU(3)$_c$ in the representation of the field where D_μ is acting on.

To obtain a prediction for m_W, we will use measurements of the Fermi constant (from muon decay), G_F, the Z mass, m_Z, and the fine-structure constant, α_{em} as input parameters. Within SMEFT, the usual expressions for these observables obtain corrections from dimension-six operators, which will propagate to the predictions for other observables. In particular, we have [58][6]

$$\left[G_F\right]_{\text{SMEFT}} = \left[G_F\right]_{\text{SM}} + \frac{1}{\sqrt{2}} \left(C_{Hl}^{(3)}{}_{11} + C_{Hl}^{(3)}{}_{22} - C_{ll} \right),$$

$$\left[m_Z^2\right]_{\text{SMEFT}} = \left[m_Z^2\right]_{\text{SM}} + \frac{1}{8} v^4 (g_1^2 + g_2^2)\, C_{HD} + \frac{1}{2} v^4 g_1 g_2\, C_{HWB},$$

$$[\alpha_{em}]_{\text{SMEFT}} = [\alpha_{em}]_{\text{SM}} - \frac{v^2 g_1^3 g_2^3}{2\pi (g_1^2 + g_2^2)^2} C_{HWB}, \tag{A.3}$$

where, at tree level, $\left[G_F\right]_{\text{SM}} = \frac{1}{\sqrt{2} v^2}$, $[m_Z^2]_{\text{SM}} = \frac{g_1^2 + g_2^2}{4} v^2$, and $[\alpha_{em}]_{\text{SM}} = \frac{1}{4\pi} \frac{g_1^2 g_2^2}{g_1^2 + g_2^2}$. The experimental values for the quantities in eq. (A.3) expressions are [3]

$$G_F = 1.1663787(6) \cdot 10^{-5}\,\text{GeV}^{-2}, \quad m_Z = 91.1876(21)\,\text{GeV}, \quad \frac{1}{\alpha_{em}} = 137.035999180(10). \tag{A.4}$$

A.1 Translation to EWPO

The traditional EWPO observables mainly constrain the flavor-diagonal couplings of the Z boson. In the mass basis, these can be written as

$$\mathcal{L}_Z = g_Z \sum_{f=u,d,e,\nu} \bar{f} \gamma_\mu \left[g_L^{(f)} P_L + g_R^{(f)} P_R \right] f Z^\mu, \tag{A.5}$$

---

[6]In principle, the SMEFT involves additional operators, $Q_{H,H\square,HW,HB,HG}$, that affect the gauge couplings, $g_{1,2,3}$ as well as the Higgs kinetic term and its vev. However, these effects can be captured by redefinitions of the gauge couplings and vev, and do not lead to measurable effects in the observables we consider.

where $g_Z = -2\,2^{1/4}\sqrt{G_F}m_Z$. The couplings $g_{L,R}^{(f)} = \left[g_{L,R}^{(f)}\right]_{\mathrm{SM}} + \delta g_{L,R}^{(f)}$ are matrices in the flavor space. The SM contributions are diagonal in flavor, $\left[g_L^{(f)}\right]_{\mathrm{SM}} = [T_3 - s_w^2 Q]\,\mathbf{1}$ and $\left[g_R^{(f)}\right]_{\mathrm{SM}} = -s_w^2 Q\,\mathbf{1}$, with T_3 and Q denoting the third component of weak isospin and the electromagnetic charge of f, respectively.[7] The shifts due to dimension-six operators are given by [64]

$$
\begin{aligned}
\delta g_L^{(\ell)} &= \left[g_L^{(\ell)}\right]_{\mathrm{SM}} \delta g_Z - \frac{v^2}{2}\left(C_{Hl}^{(1)} + C_{Hl}^{(3)}\right) - \delta s_w^2\,\mathbf{1}\,, \\
\delta g_L^{(\nu)} &= \left[g_L^{(\nu)}\right]_{\mathrm{SM}} \delta g_Z - \frac{v^2}{2}\left(C_{Hl}^{(1)} - C_{Hl}^{(3)}\right)\,, \\
\delta g_L^{(u)} &= \left[g_L^{(u)}\right]_{\mathrm{SM}} \delta g_Z - \frac{v^2}{2}V\left(C_{Hq}^{(1)} - C_{Hq}^{(3)}\right)V^\dagger + \frac{2}{3}\delta s_w^2\,\mathbf{1}\,, \\
\delta g_L^{(d)} &= \left[g_L^{(d)}\right]_{\mathrm{SM}} \delta g_Z - \frac{v^2}{2}\left(C_{Hq}^{(1)} + C_{Hq}^{(3)}\right) - \frac{1}{3}\delta s_w^2\,\mathbf{1}\,, \\
\delta g_R^{(\ell)} &= \left[g_R^{(\ell)}\right]_{\mathrm{SM}} \delta g_Z - \frac{v^2}{2}C_{He} - \delta s_w^2\,\mathbf{1}\,, \\
\delta g_R^{(u)} &= \left[g_R^{(u)}\right]_{\mathrm{SM}} \delta g_Z - \frac{v^2}{2}C_{Hu} + \frac{2}{3}\delta s_w^2\,\mathbf{1}\,, \\
\delta g_R^{(d)} &= \left[g_R^{(d)}\right]_{\mathrm{SM}} \delta g_Z - \frac{v^2}{2}C_{Hd} - \frac{1}{3}\delta s_w^2\,\mathbf{1}\,,
\end{aligned}
\tag{A.6}
$$

where $s_w^2 = \sin^2\theta_w$ is expressed in terms of G_F, m_Z and α_{em} as

$$
s_w^2 = \frac{1}{2}\left[1 - \sqrt{1 - \frac{4\pi\alpha_{em}}{\sqrt{2}G_F m_Z^2}}\,\right]\,,
\tag{A.7}
$$

and

$$
\begin{aligned}
\delta g_Z &= -\frac{v^2}{2}\left[\frac{1}{2}C_{HD} + C_{Hl}^{(3)}{}_{11} + C_{Hl}^{(3)}{}_{22} - \frac{1}{2}C_{\,2112}^{\,ll} - \frac{1}{2}C_{\,1221}^{\,ll}\right]\,, \\
\delta s_w^2 &= v^2\frac{c_w s_w}{s_w^2 - c_w^2}\left[C_{HWB} + c_w s_w\left(\frac{1}{2}C_{HD} + C_{Hl}^{(3)}{}_{11} + C_{Hl}^{(3)}{}_{22} - \frac{1}{2}C_{\,2112}^{\,ll} - \frac{1}{2}C_{\,1221}^{\,ll}\right)\right]\,,
\end{aligned}
\tag{A.8}
$$

with $c_w = \cos\theta_w$. In addition, several electroweak precision observables are sensitive to the (left-handed) couplings of the W boson, which can be written as

$$
\mathcal{L}_W = -\frac{g_W}{\sqrt{2}}\left[\bar{u}\gamma^\mu\left(g_L^{Wq}P_L + g_R^{Wq}P_R\right)d + \bar{\nu}\gamma^\mu\left(g_L^{W\ell}P_L\right)e\right]W_\mu^+ + \text{h.c.}
\tag{A.9}
$$

Here $g_W = \frac{\sqrt{4\pi\alpha_{em}}}{s_w}$ and

$$
\begin{aligned}
g_L^{Wq} &= V\left[\left(1 + \frac{\delta s_w^2}{2s_w^2} + \frac{v^2}{2}\frac{c_w}{s_w}C_{HWB}\right)\mathbf{1} + v^2 C_{Hq}^{(3)}\right]\,, \\
g_R^{Wq} &= \frac{v^2}{2}C_{Hud}\,, \\
g_L^{W\ell} &= \left(1 + \frac{\delta s_w^2}{2s_w^2} + \frac{v^2}{2}\frac{c_w}{s_w}C_{HWB}\right)\mathbf{1} + v^2 C_{Hl}^{(3)}\,.
\end{aligned}
\tag{A.10}
$$

---

[7]Our normalization is such that e.g. $T_3 = 1/2$ and $Q = 2/3$ for $f = u$.

Finally, the expression for m_W in SMEFT is given by

$$\frac{\delta m_W^2}{m_W^2} = v^2 \, \frac{s_w c_w}{s_w^2 - c_w^2} \left[2 \, C_{HWB} + \frac{c_w}{2 s_w} C_{HD} + \frac{s_w}{c_w} \left(2 \, C_{Hl}^{(3)} - \hat{C}_{ll} \right) \right]. \tag{A.11}$$

A.2 Translation to low-energy basis

For the decays of kaon and pion, and β decays, the often used low-energy effective Lagrangian is given by [40, 51, 76, 117]

$$\begin{aligned}
\mathcal{L}_\beta = -\frac{G_F}{\sqrt{2}} V_{uD} \Bigg[& \bar{\ell}\gamma_\mu(1-\gamma_5)\nu_\ell \bigg(\left(1 + \epsilon_L^{\ell D} - \epsilon_L^\mu \right) \, \bar{u}\gamma^\mu(1-\gamma_5)D + \epsilon_R^{\ell D} \, \bar{u}\gamma^\mu(1+\gamma_5)D \bigg) \\
& + \bar{\ell}(1-\gamma_5)\nu_\ell \left(\epsilon_S^{\ell D} \, \bar{u}D + \epsilon_P^{\ell D} \, \bar{u}\gamma_5 D \right) + \epsilon_T^{\ell D} \, \bar{\ell}\sigma_{\mu\nu}(1-\gamma_5)\nu_\ell \, \bar{u}\sigma^{\mu\nu}(1-\gamma_5)D \Bigg] + \text{h.c.},
\end{aligned} \tag{A.12}$$

where $D = \{d, s\}$. The tree-level expressions for the ϵ couplings in terms of SMEFT coefficients are given by

$$\begin{aligned}
V_{uD}\,\epsilon_L^{\ell D} &= v^2 \left[V\, C_{Hq}^{(3)} \right]_{1D} - v^2 \left[V C_{lq}^{(3)} \right]_{\ell\ell 1D} + v^2 V_{uD} \left[C_{Hl}^{(3)} \right]_{\ell\ell}, \\
&= \frac{v^2}{2} \left[V C_{Hq}^{(d)} - C_{Hq}^{(u)} V \right]_{uD} - \frac{v^2}{2} \left[V C_{lq}^{(d)} - C_{lq}^{(u)} V \right]_{\ell\ell uD} + v^2 V_{uD} \left[C_{Hl}^{(3)} \right]_{\ell\ell} \\
V_{uD}\,\epsilon_R^{\ell D} &= \frac{v^2}{2} \left[C_{Hud} \right]_{1D}, \\
V_{uD}\,\epsilon_S^{\ell D} &= -\frac{v^2}{2} \left[V C_{ledq}^\dagger + C_{lequ}^{(1)\,\dagger} \right]_{\ell\ell 1D} = -\frac{v^2}{2} \left[V C_{ledq}^\dagger + \bar{C}_{lequ}^{(1)\,\dagger} V \right]_{\ell\ell 1D}, \\
V_{uD}\,\epsilon_P^{\ell D} &= +\frac{v^2}{2} \left[V C_{ledq}^\dagger - C_{lequ}^{(1)\,\dagger} \right]_{\ell\ell 1D} = +\frac{v^2}{2} \left[V C_{ledq}^\dagger - \bar{C}_{lequ}^{(1)\,\dagger} V \right]_{\ell\ell 1D}, \\
V_{uD}\,\epsilon_T^{\ell D} &= -\frac{v^2}{2} \left[C_{lequ}^{(3)\,\dagger} \right]_{\ell\ell 1D} = -\frac{v^2}{2} \left[\bar{C}_{lequ}^{(3)\,\dagger} V \right]_{\ell\ell 1D}.
\end{aligned} \tag{A.13a}$$

Finally, ϵ_L^μ arises from the SMEFT correction to G_F as extracted from muon decay, see eq. (A.3), and is given by

$$\epsilon_L^\mu = v^2 \left[C_{Hl}^{(3)}{}_{11} + C_{Hl}^{(3)}{}_{22} - C_{ll}{}_{2112} \right]. \tag{A.14}$$

B Experimental and theoretical input to observables

B.1 Electroweak precision observables

The observables used are listed in table 12. The table includes 'traditional' EWPOs measured at LEP and SLC in the first column, while the second column involves several observables measured at hadron colliders. These additional constraints are needed when going beyond flavor-universal SMEFT scenarios. Observables that may be less familiar are defined by

$$R_{uc} = \frac{\Gamma(Z \to \bar{u}u) + \Gamma(Z \to \bar{c}c)}{\sum_q \Gamma(Z \to \bar{q}q)}, \quad R_{Wc} = \frac{\Gamma(W \to cs)}{\Gamma(W \to ud) + \Gamma(W \to cs)}, \quad R_\sigma^2 = \frac{\sigma_t}{\sigma_t^{\text{SM}}}, \tag{B.1}$$

Table 12. Input parameters and EWPOs used in the analysis. Each shaded block indicates a set of correlated observables. Entries without an explicit SM prediction share their SM value with the observable above.

where σ_t is the single-top production cross section in the t channel. Furthermore, $g_{V,A}^{(q)} = g_L^{(q)} \pm g_R^{(q)}$ and $A_4(a-b)$ correspond to the forward-backward asymmetry in $pp \to \bar{\ell}\ell$ in the rapidity range $a \leq Y \leq b$ [67]. For each observable, we include the leading tree-level SMEFT corrections up to $\mathcal{O}(1/\Lambda^2)$. We follow ref. [64] for the traditional EWPOs, while we use the results of [67] for the measurements of A_4. SMEFT corrections for the remaining observables depend on the modified couplings of W and Z and can be straightforwardly derived from their definitions.

B.2 Low-energy charged-current observables

B.2.1 Neutron and nuclear β decays

We include measurements of $0^+ \to 0^+$ transitions, neutron decay, as well as decay correlation measurements, following ref. [51]. For measurements of neutron decays, the observables include the lifetime, as well as several correlation coefficients, $\tilde{A}_n$, $\tilde{B}_n$, a_n, $\tilde{a}_n$, and λ_{AB}. The included $\mathcal{F}t$ values from superallowed decays are listed in table 13, while the correlation measurements used in the nuclei are collected in table 14. For definitions of the observables, see ref. [51]. In addition to these observables, the fit includes data from measurements of mirror nuclei, as described in [51]. However, the impact of these observables is small in the scenario we consider, while they are more important in models involving right-handed neutrinos. The explicit values of the experimental input summarized above can be found in ref. [51], in particular in their tables 1 (for the mirror transitions), 8 (for $0^+ \to 0^+$), as well

Table 14. Data from correlation measurements in pure Fermi and pure Gamow-Teller decays used in the fits. Table adapted from [51].

as 9 and 10 (for the neutron decay and correlation measurements). Finally, we include the measurement of the ratio of the axial and vector form factors in $\Lambda \to p e \nu_e$ [3].

As mentioned in section 2.2.1 the theoretical expressions do not just involve the SM and SMEFT parameters, but also depend on several hadronic and nuclear matrix elements. The relevant hadronic input for the SM consists of the vector and axial nucleon charges, g_V and g_A, and radiative corrections, $\Delta_R^{V,A}$, while the contributions due to BSM interactions require the scalar and tensor charges, g_S, g_T. Pseudoscalar interactions are suppressed by $\mathcal{O}(m_e \Lambda_\chi / m_\pi^2)$, and we neglect their contributions to β decays. We summarize these hadronic parameters in the first column of table 15.

In addition, the fit includes several ratios of Gamow-Teller (GT) and Fermi (F) matrix elements, $\rho = \frac{g_A}{g_V} \frac{M_{GT}}{M_F}$, which appear in the mirror transitions mentioned above. Finally, ref. [51] included the parameters η_1 and $\eta_{2,3}$ to capture theoretical uncertainties due to radiative corrections δ'_R, and contributions dependent on nuclear structure, δ_{NS}, respectively. We treat $\eta_{1,2,3}$ as Gaussian with a mean of $\mu(\eta_{1,2,3}) = 0$ and $\sigma(\eta_{1,2,3}) = 1$, while we do not include any theoretical input of ρ_i which is determined by the fit.

B.2.2 Kaon and pion decays

The experimental data used for the decays of pion and kaon are collected in table 16. Apart from the two-body decay rates (the first column), we include determinations of $V_{us}^\ell f_+(0)$ from the $K \to \pi e \nu$ and $K \to \pi \mu \nu$ rates and measurements of the differential distributions (second column). The latter include a determination of the tensor interaction, $\epsilon_T^{s\mu}$, as well as a determination of $\log C$, which is sensitive to scalar interactions. As $V_{us}^\ell f_+(0)$ has been determined assuming the SM form of the decay distribution, we follow [40] to obtain the correlation between these rates and the tensor interaction. Using the input from ref. [57],

Baryon decays			K and π decays		
g_A	1.246(28)	[12]	$f_+(0)$	0.9698(17)	[12]
g_S	1.02(10)	[12]	$\frac{f_{K^\pm}}{f_{\pi^\pm}}$	1.1932(21)	[12]
g_T	0.989(34)	[12]	$f_{K^\pm}$	155.7(3) MeV	[12]
Δ_R^V	0.02467(22)	[4]	RC$_\pi$	0.0332(3)	[14]
$\frac{\Delta_R^A - \Delta_R^V}{2}$	0.00013(13)	[98]	c_1^π	$-2.4(5)$	[132]
$g_1/f_1\big|_{\Lambda \to p}$	0.72(7)	[40, 133]	Δ_{CT}	$-0.0035(80)$	[134]
			$\frac{B_T(0)}{f_+(0)}$	0.68(3)	[135]

Table 15. The hadronic input that enters β decays. We approximate $g_V = 1$, which holds with high precision. Whenever appropriate, the value on a renormalization scale $\mu = 2\,\text{GeV}$ is given.

P_{l2}			K_{l3}		
Observable	value	Ref.	Observable	value	Ref.
R_π	$1.2344(30) \cdot 10^{-4}$	[136]	$|\tilde{V}_{us}^e f_+^K(0)|$	0.21626(40)	[57]
R_K	$2.488(9) \cdot 10^{-5}$	[3]	$|\tilde{V}_{us}^\mu f_+^K(0)|$	0.21667(52)	[57]
$\Gamma(K_{\mu2})$	$5.134(10) \cdot 10^{-7} s^{-1}$	[3]	$\log C$	0.1985(70)	[137]
$\text{Br}(\pi_{\mu2})$	0.9998770(4)	[3]	$2\epsilon_T^{s\mu} \frac{B_T(0)}{f_+(0)}$	0.0007(71)	[138]
τ_{π^+}	$2.6033(5) \cdot 10^{-8} s$	[3]			

Table 16. The experimental input used for kaon and π decays. Note that the determinations of $|\tilde{V}_{us}^\ell f_+^K(0)|$ involve a correlation that is not shown in the table. The ratio $R_\mu = \Gamma(K_{\mu2})/\Gamma(\pi_{\mu2})$, with $\Gamma(\pi_{\mu2}) = \text{Br}(\pi_{\mu2})/\tau_{\pi^+}$, is derived from the table.

shown in table 16, we then obtain the following correlation matrix

$$\begin{pmatrix} |V_{us}^e f_+(0)| \\ |V_{us}^\mu f_+(0)| \\ -2\epsilon_T^{s\mu} \frac{B_T(0)}{f_+(0)} \end{pmatrix} = \begin{pmatrix} 0.21634(40) \\ 0.21652(52) \\ 0.0007(71) \end{pmatrix}, \qquad \text{Corr} = \begin{pmatrix} 1 & 0.57 & 0 \\ 0.57 & 1 & 0.44 \\ 0 & 0.44 & 1 \end{pmatrix}. \qquad \text{(B.2)}$$

We follow [40] for the theoretical expressions of the observables and summarize the relevant hadronic input in the second column of table 15. The two-body decays depend on the decay constants $f_{\pi,K}$, the radiative corrections $\delta_{em}^{P\ell}$, and $S_{ew} = 1.0232(3)$, which captures the SM short-distance corrections. The radiative corrections can be expressed in terms of known functions and a low-energy constant, c_1^π, shown in table 15, see eq. (10) of ref. [40] and [132, 139] for additional details. Instead, the three-body decays depend on the form factor $f_+(0)$, as well as the parameters Δ_{CT} and B_T. The latter two parameters enter into the expression for the shape of the differential distributions that are sensitive to scalar and tensor interactions. Finally, pion β decay depends on radiative corrections, captured by the factor RC$_\pi$.

B.3 Collider probes

C Flavor constraints

In this appendix, we further motivate the flavor structure of the SMEFT operators adopted in section 3.2 by considering limits from leptonic and semileptonic flavor-changing neutral-current decays of B, D, and K mesons. This appendix does not aim to be exhaustive, but to provide a justification of neglecting off-diagonal components.

FCNC processes are more easily analyzed in LEFT, for which we adopt the operator basis defined in ref. [50]. Using the notation of section 3.2, the tree-level matching coefficients onto neutral current LEFT vector operators with charged leptons $\ell \in \{e, \mu, \tau\}$ are given by

$$
\begin{aligned}
\left[L_{\rm VLL}^{eu}\right]_{\ell\ell ij} &= \left[C_{lq}^{(u)}\right]_{\ell\ell ij} - 4\sqrt{2}G_F \left[g_L^{(e)}\right]_{\ell\ell} \left[g_L^{(u)}\right]_{ij}, \\
\left[L_{\rm VLL}^{ed}\right]_{\ell\ell ij} &= \left[C_{lq}^{(d)}\right]_{\ell\ell ij} - 4\sqrt{2}G_F \left[g_L^{(e)}\right]_{\ell\ell} \left[g_L^{(d)}\right]_{ij}, \\
\left[L_{\rm VRR}^{eu}\right]_{\ell\ell ij} &= \left[C_{eu}\right]_{\ell\ell ij} - 4\sqrt{2}G_F \left[g_R^{(e)}\right]_{\ell\ell} \left[g_R^{(u)}\right]_{ij}, \\
\left[L_{\rm VRR}^{ed}\right]_{\ell\ell ij} &= \left[C_{ed}\right]_{\ell\ell ij} - 4\sqrt{2}G_F \left[g_R^{(e)}\right]_{\ell\ell} \left[g_R^{(d)}\right]_{ij}, \\
\left[L_{\rm VLR}^{eu}\right]_{\ell\ell ij} &= \left[C_{lu}\right]_{\ell\ell ij} - 4\sqrt{2}G_F \left[g_L^{(e)}\right]_{\ell\ell} \left[g_R^{(u)}\right]_{ij}, \\
\left[L_{\rm VLR}^{ed}\right]_{\ell\ell ij} &= \left[C_{ld}\right]_{\ell\ell ij} - 4\sqrt{2}G_F \left[g_L^{(e)}\right]_{\ell\ell} \left[g_R^{(d)}\right]_{ij}, \\
\left[L_{\rm VLR}^{ue}\right]_{\ell\ell ij} &= \left[V C_{qe} V^\dagger\right]_{\ell\ell ij} - 4\sqrt{2}G_F \left[g_R^{(e)}\right]_{\ell\ell} \left[g_L^{(u)}\right]_{ij}, \\
\left[L_{\rm VLR}^{de}\right]_{\ell\ell ij} &= \left[C_{qe}\right]_{\ell\ell ij} - 4\sqrt{2}G_F \left[g_R^{(e)}\right]_{\ell\ell} \left[g_L^{(d)}\right]_{ij},
\end{aligned}
\tag{C.1}
$$

with the Z couplings in the SMEFT given in eqs. (A.5) and (A.6). In eq. (C.1) we listed the contributions from the four-fermion operators $C_{lq}^{(u)}$ and $C_{lq}^{(d)}$, which also induce low-energy

charged-current processes. For completeness, we also included the remaining semileptonic operators C_{eu}, C_{ed}, C_{lu}, C_{ld}, and C_{qe}, which do not contribute to the CC decays. In the Standard Model, off-diagonal couplings arise at one loop and, because of the GIM mechanism, vanish for degenerate quark masses.

The neutral-current LEFT operators involving neutrinos are

$$
\begin{aligned}
\left[L_{\mathrm{VLL}}^{\nu u}\right]_{\nu_\ell \nu_\ell ij} &= \left[V C_{lq}^{(d)} V^\dagger\right]_{\nu_\ell \nu_\ell ij} - 4\sqrt{2} G_F \left[g_L^{(\nu)}\right]_{\nu_\ell \nu_\ell} \left[g_L^{(u)}\right]_{ij}, \\
\left[L_{\mathrm{VLL}}^{\nu d}\right]_{\nu_\ell \nu_\ell ij} &= \left[V^\dagger C_{lq}^{(u)} V\right]_{\nu_\ell \nu_\ell ij} - 4\sqrt{2} G_F \left[g_L^{(\nu)}\right]_{\nu_\ell \nu_\ell} \left[g_L^{(d)}\right]_{ij}, \\
\left[L_{\mathrm{VLR}}^{\nu u}\right]_{\nu_\ell \nu_\ell ij} &= \left[C_{lu}\right]_{\ell\ell ij} - 4\sqrt{2} G_F \left[g_L^{(\nu)}\right]_{\nu_\ell \nu_\ell} \left[g_R^{(u)}\right]_{ij}, \\
\left[L_{\mathrm{VLR}}^{\nu d}\right]_{\nu_\ell \nu_\ell ij} &= \left[C_{ld}\right]_{\ell\ell ij} - 4\sqrt{2} G_F \left[g_L^{(\nu)}\right]_{\nu_\ell \nu_\ell} \left[g_R^{(d)}\right]_{ij}.
\end{aligned} \tag{C.2}
$$

For scalar and tensor operators, neglecting the quark and lepton SM Yukawa couplings, we get

$$
\left[L_{\mathrm{SRR}}^{eu}\right]_{\ell\ell ji} = -\left[\bar{C}_{lequ}^{(1)}\right]_{\ell\ell ji}, \quad \left[L_{\mathrm{SRL}}^{ed}\right]_{\ell\ell ji} = \left[C_{ledq}\right]_{\ell\ell ji}, \quad \left[L_{\mathrm{TRR}}^{eu}\right]_{\ell\ell ji} = -\left[\bar{C}_{lequ}^{(3)}\right]_{\ell\ell ji}, \tag{C.3}
$$

with $L_{\mathrm{SRR}}^{ed} = L_{\mathrm{SRL}}^{eu} = L_{\mathrm{TRR}}^{ed} = 0$. We neglect contributions from dimension-6 corrections to the Yukawa couplings, which do not play a role in our analysis. Using the matching equations in eqs. (C.1), (C.2), and (C.3) we can derive constraints on the off-diagonal components of the SMEFT coefficients from FCNC decays of the kaon, B, and D meson.

C.1 Kaon decays

The coefficients $\left[C_{Hq}^{(d)}\right]_{12,\,21}$, $\left[C_{lq}^{(d)}\right]_{\ell\ell 12,\,21}$, and $[C_{ledq}]_{\ell\ell 12,\,21}$ contribute to the decays $K_L \to \ell^+\ell^-$ and $K \to \pi\ell^+\ell^-$ at tree level. To check the constraints on these couplings, we used packages flavio [145] and wilson [146], which include branching ratios $K_L \to e^+e^-$ and $K_L \to \mu^+\mu^-$. The bounds can be improved by using the refined analysis of ref. [147]. Assuming only one SMEFT operator at a time, we find very strong limits on the four-fermion operators

$$
\begin{aligned}
\left|C_{lq\atop 1112}^{(d)}\right| &< 2.4 \cdot 10^{-3}\,\mathrm{TeV}^{-2}, & \left|C_{lq\atop 2212}^{(d)}\right| &< 2.2 \cdot 10^{-4}\,\mathrm{TeV}^{-2}, \\
\left|C_{ledq\atop 1112}\right| &< 8.2 \cdot 10^{-7}\,\mathrm{TeV}^{-2}, & \left|C_{ledq\atop 2212}\right| &< 1.6 \cdot 10^{-6}\,\mathrm{TeV}^{-2},
\end{aligned} \tag{C.4}
$$

at 99.7% confidence level. Similar constraints apply to the coefficients with $1 \leftrightarrow 2$ on the quark flavor indices. As discussed in section 3.2, while $[C_{lq}^{(d)}]_{\ell\ell 12}$ and $[C_{ledq}]_{\ell\ell 12}$ could in principle affect nuclear, kaon, and pion charged current decays, the flavor constraints are so strong that it is safe to neglect their contributions. The bounds in eq. (C.4) can be weakened by turning on several coefficients at the same time. However, performing a global analysis would also require the inclusion of other observables, such as $K_S \to \ell^+\ell^-$ or $K \to \pi\ell^+\ell^-$, which would provide additional constraining power.

Vertex corrections $C_{Hq}^{(d)}$ and C_{Hd} contribute to semileptonic processes with charged leptons or neutrinos in the final state. Including the branching ratios $K^+ \to \pi^+\bar\nu\nu$ and

$K_L \to \pi^0 \bar{\nu}\nu$, we find

$$\left| C^{(d)}_{\substack{Hq \\ 12}} \right| < 1.0 \cdot 10^{-4}\,\mathrm{TeV}^{-2}, \qquad \left| C_{\substack{Hd \\ 12}} \right| < 1.2 \cdot 10^{-4}\,\mathrm{TeV}^{-2}, \tag{C.5}$$

which once again justifies neglecting $s - d$ off-diagonal components.

Finally, as shown in eqs. (3.10) and (C.2), $C^{(u)}_{lq}$ induces couplings of d-quarks to neutrinos. For example, at tree level,

$$\left[L^{\nu d}_{\mathrm{VLL}} \right]_{\nu_\ell \nu_\ell 12} = C^{(u)}_{\substack{lq \\ \ell\ell 12}} + \lambda \left(C^{(u)}_{\substack{lq \\ \ell\ell 11}} - C^{(u)}_{\substack{lq \\ \ell\ell 22}} \right) + \dots, \tag{C.6}$$

with $K \to \pi\nu\nu$ enforcing

$$\left| \left[L^{\nu d}_{\mathrm{VLL}} \right]_{\nu_\ell \nu_\ell 12} \right| < 9.7 \cdot 10^{-5}\,\mathrm{TeV}^{-2}. \tag{C.7}$$

This constraint on the diagonal couplings can be avoided by setting the 11 and 22 components of $C^{(u)}_{lq}$ to be equal.

C.2 B decays

Nuclear β decays as well as the charged-current decays of pions and kaons are minimally affected by couplings to b quarks. In the notation of eqs. (3.5) and (3.6), we get

$$\epsilon^{d\ell}_L = \frac{v^2}{2} \frac{V_{ub}}{V_{ud}} \left(C^{(d)}_{\substack{Hq \\ 31}} - C^{(d)}_{\substack{lq \\ \ell\ell 31}} \right), \qquad \epsilon^{s\ell}_L = \frac{v^2}{2} \frac{V_{ub}}{V_{us}} \left(C^{(d)}_{\substack{Hq \\ 32}} - C^{(d)}_{\substack{lq \\ \ell\ell 32}} \right). \tag{C.8}$$

The V_{ub} suppression is such that, for coefficients of $\mathcal{O}(1\,\mathrm{TeV}^{-2})$, $\epsilon^{d\ell}_L$ and $\epsilon^{s\ell}_L$, are about $1 \cdot 10^{-4}$ and $5 \cdot 10^{-4}$, respectively, already too small to explain the Cabibbo anomaly. The strong constraints from $B \to \mu\mu$, $B \to K\mu\mu$, and $B \to \pi\mu\mu$ ensure that the contributions of the bs and bd components of $C^{(d)}_{Hq}$ and $C^{(d)}_{lq}$ are irrelevant to the CLEW observables.

C.3 D and top decays

In the case of D decays, the experimental limits on the purely leptonic branching ratios are [3]

$$\mathrm{BR}(D^0 \to e^+ e^-) < 7.9 \cdot 10^{-8}, \qquad \mathrm{BR}(D^0 \to \mu^+ \mu^-) < 6.2 \cdot 10^{-9}, \tag{C.9}$$

while the 90% CL limits of the semileptonic branching ratios are

$$\mathrm{BR}(D^+ \to \pi^+ e^+ e^-) < 1.1 \cdot 10^{-6}, \qquad \mathrm{BR}(D^+ \to \pi^+ \mu^+ \mu^-) < 6.7 \cdot 10^{-8}, \tag{C.10}$$

$$\mathrm{BR}(D_s \to K^+ e^+ e^-) < 3.7 \cdot 10^{-6}, \qquad \mathrm{BR}(D_s \to K^+ \mu^+ \mu^-) < 1.4 \cdot 10^{-7}. \tag{C.11}$$

The short-distance contribution to the branching ratio $D \to \ell^+ \ell^-$ is given by

$$\begin{aligned}
\mathrm{BR}(D^0 \to \ell^+ \ell^-) = {} & \frac{\tau_{D^0}}{32\pi} \sqrt{1 - \frac{4m_\ell^2}{m_{D^0}^2}} m_{D^0} f_D^2 m_\ell^2 \\
& \times \left[\left| B + \frac{m_{D^0}^2}{2m_\ell(m_c + m_u)} D \right|^2 + \left(1 - \frac{4m_\ell^2}{m_{D^0}^2} \right) \left| \frac{m_{D^0}^2}{2m_\ell(m_c + m_u)} C \right|^2 \right],
\end{aligned} \tag{C.12}$$

where f_D is the D meson decay constant, for which we take the FLAG average $f_D = 212(1)\,\mathrm{MeV}$ [148]. B, C and D are combinations of matching coefficients given by

$$B = (L_{\mathrm{VLL}}^{eu} - L_{\mathrm{VLR}}^{eu} + L_{\mathrm{VRR}}^{eu} - L_{\mathrm{VLR}}^{ue})_{\ell\ell12} \,, \tag{C.13}$$

$$C = (L_{\mathrm{SRR}}^{eu})_{\ell\ell12} - (L_{\mathrm{SRL}}^{eu})_{\ell\ell12} + (L_{\mathrm{SRL}}^{eu*})_{\ell\ell21} - (L_{\mathrm{SRR}}^{eu*})_{\ell\ell21} \,, \tag{C.14}$$

$$D = (L_{\mathrm{SRR}}^{eu})_{\ell\ell12} - (L_{\mathrm{SRL}}^{eu})_{\ell\ell12} - (L_{\mathrm{SRL}}^{eu*})_{\ell\ell21} + (L_{\mathrm{SRR}}^{eu*})_{\ell\ell21} \,. \tag{C.15}$$

The expression for semileptonic decays $D \to P\ell^+\ell^-$ is more complicated and depends on vector, scalar, and tensor form factors. See, for example, ref. [149] for a general parameterization.

Considering the bounds on the leptonic branching ratios, assuming the SMEFT contribution to saturate the experimental bound, and turning on one operator at a time we obtain

$$\left| C_{lq}^{(u)} \right|_{1112} < 41.5\,\mathrm{TeV}^{-2}\,, \qquad\qquad \left| \bar{C}_{lequ}^{(1)} \right|_{1112} < 0.01\,\mathrm{TeV}^{-2}\,,$$

$$\left| C_{lq}^{(u)} \right|_{2212} < 0.06\,\mathrm{TeV}^{-2}\,, \qquad\qquad \left| \bar{C}_{lequ}^{(1)} \right|_{2212} < 0.006\,\mathrm{TeV}^{-2}\,,$$

$$\left| C_{Hq}^{(u)} \right|_{12} < 0.06\,\mathrm{TeV}^{-2}\,, \qquad\qquad \left| C_{Hu}^{} \right|_{12} < 0.06\,\mathrm{TeV}^{-2}\,. \tag{C.16}$$

The limit on the electron coupling $C_{lq}^{(u)}$ is particularly weak because of the chiral suppression in $D^0 \to e^+e^-$. Adding $D \to \pi e^+e^-$ would constrain $[C_{lq}^{(u)}]_{1112}$ at a level similar to the other vector couplings in eq. (C.16). Comparing the bounds in eq. (C.16) with the results of section 7, we see that the constraints on u-c FCNC are not strong enough to exclude contributions from u-c operators to the neutron and nuclear β decays, pion, and kaon CC decays at a level comparable with current uncertainties. Therefore, one could imagine performing a joint analysis of u-c FCNC processes, c-d and c-s CC transitions, neutron β decays, and pion and kaon decays. Here, for simplicity, we choose to focus only on processes without charm and to set u-c FCNC coefficients to zero.

As shown in eq. (3.9), top flavor-changing couplings can enter low-energy charged-current observables at $\mathcal{O}(\lambda)$. FCNC top decays in SMEFT were studied in refs. [150, 151]. Focusing on the Z couplings induced by $C_{Hq}^{(u)}$ and C_{Hu}, the branching ratio at LO in QCD becomes

$$\mathrm{Br}(t \to Zq_i) = \frac{2}{c_w^2} f\left(\frac{m_Z^2}{m_t^2}\right) \left[f\left(\frac{m_W^2}{m_t^2}\right) \right]^{-1} \left(\left[\delta g_R^{(u)}\right]_{i3}^2 + \left[\delta g_L^{(u)}\right]_{i3}^2 \right) \,,$$

$$f(x) = \frac{1}{x}(1-x)^2(1+2x) \,. \tag{C.17}$$

The most recent limits on the branching ratios from the ATLAS collaboration are [152]

$$\mathrm{Br}(t \to Zu) < 13 \cdot 10^{-5}\,, \qquad \mathrm{Br}(t \to Zc) < 6.2 \cdot 10^{-5}\,, \tag{C.18}$$

implying

$$\frac{v^2}{2}\left[C_{Hq}^{(u)}\right]_{13} < 8.4 \cdot 10^{-3}\,, \qquad \frac{v^2}{2}\left[C_{Hq}^{(u)}\right]_{23} < 5.8 \cdot 10^{-3}\,. \tag{C.19}$$

When multiplied by V_{ts}/V_{us}, the contribution to $\epsilon_L^{s\ell}$ is of order 10^{-3} and negligible.
